The use of eye-tracking for understanding neuropsychiatric conditions and special populations in general is attractive for a number of reasons. First, at its essence, eye-tracking is a method for seeing how others see, providing a robust, quantitative measure of where someone is looking. Since where someone is looking is highly correlated to where that person’s attention is deployed, eye-tracking can be used to understand temporally changing cognitive processes as they unfold (with caveats; see section “[Limitations of Eye-Tracking](#)”). Second, eye-tracking is today a relatively noninvasive and easily tolerated experimental technology. As compared to the original systems of the early nineteenth century, which were often so uncomfortable that the eye had to be anesthetized with cocaine, modern desktop-mounted video oculography eye-tracking systems (see section “[Types of Eye-Trackers](#)”) can obtain precise measurements of the eye without ever touching any part of the participant. Third, the oculomotor system is early maturing and highly preserved neurophysiological control system. This means that eye-tracking can be an applicable and appropriate technique across the vast cognitive, behavioral, and physiological heterogeneity found in many neuropsychiatric conditions.

The earliest published work using eye-tracking to study individuals with ASD appeared in 2002 (Klin et al. 2002; Pelphrey et al. 2002; van der Geest et al. 2002a; van der Geest et al. 2002b). The general pattern of this work suggested that in many cases, the visual scanning strategies of individuals with ASD are significantly different than that of controls. These initial reports found, for example, that older adolescents and adults with

ASD tended to look more at the mouth and less at the eyes in comparison to control individuals. They also highlighted relationships between communicative ability and scanning patterns, with the somewhat surprising finding that individuals with ASD who looked more at the mouth were actually more communicatively capable than those who looked less. Additional studies have largely confirmed the atypical nature of visual scanning strategies in individuals with ASD, especially under conditions where choices in attentional selection must be made between social and nonsocial stimuli. Results of several studies show, for instance, decreased attention toward social actors, people in general, and faces, and increased attention toward nonsocial background elements of scenes (e.g., Jones et al. 2008; Klin et al. 2002; Pierce et al. 2011; Riby and Hancock 2009; Shic et al. 2011). Other studies also highlight decreased sensitivity in individuals with ASD to communicative and social aspects of interactions, such as gaze cues and shared activities (Freeth et al. 2009; Riby and Doherty 2011; Shic et al. 2011). Finally, eye-tracking studies have related inefficient social information-gathering strategies to poor performance in face recognition tasks in both adults (Spezio et al. 2007) and toddlers and children with ASD (Chawarska and Shic, 2009). Taken together, these studies provide evidence for atypical visual exploratory behaviors in individuals with ASD and promote the use of eye-tracking technology in efforts toward understanding the mechanisms underlying atypically developing social skills in individuals with ASD.

However, it is important to note that the use of eye-tracking in studying ASDs is a developing and emerging field. While originally there was a great deal of enthusiasm regarding atypical distributions of attention toward specific elements of the face (e.g., proportions of mouth and eye scanning), recent reports have highlighted the complex interrelationships between cognitive, social, and behavioral phenotypes and visual exploratory behavior (Chawarska and Shic 2009; Norbury et al. 2009). Indeed, several studies did not replicate atypical patterns of looking at faces or social scenes, even as early as 2002 (van der Geest et al. 2002a, b). The reasons for these disagreements are

currently active areas of exploration. However, there are likely several factors involved, such as heterogeneity of sample populations, variety of experimental paradigms and contexts, and inconsistencies across research sites in use of pre-processing methodology and analytical techniques. Nevertheless, eye-tracking has been and continues to be a powerful methodology for understanding the nature of ASD; as more research using eye-tracking is conducted, its application will likely extend further toward questions regarding the heterogeneity of behavioral and visual exploratory activities in ASD.

Types of Eye-Trackers

There are several types of eye-tracking technologies still in widespread use (Duchowski 2007). However, recently, psychological and behavioral studies of individuals with ASD and other neuropsychiatric conditions have largely begun to rely exclusively on the use of remote video oculography (VOG) methods. In modern video oculography, a video camera or multiple video cameras are positioned so as to be able to obtain a clear image of the participant's eye. These cameras, typically linked up to either specialized hardware or a computer, employ sophisticated computational algorithms in order to extract from the video the position of the participant's pupil(s). In the most common methodology, infrared filters are used to remove contaminating light sources which otherwise complicate signal analysis extraction of the pupil location. In these infrared systems, additional infrared light sources, which are largely invisible to the human eye, are used in order to generate "glints" or corneal reflections which serve as a reference coordinate system for the pupil that is more invariant to participant motion. Additionally, the eye and face of the participants can be lit by on-camera-axis lighting or off-camera-axis lighting. On-camera-axis lighting generates a form of infrared video oculography called "bright-pupil" eye-tracking. In bright-pupil eye-tracking, illumination of the eye causes a "red-eye effect" (similar to what occurs when a flash is reflected off someone's eye in a camera photograph). This makes the pupil appear bright. In off-camera-axis lighting,

the pupil remains dark because infrared light is not reflected, resulting in a "dark pupil." Though some manufacturers suggest one form of lighting is superior for certain individuals (e.g., for those with light blue eyes as compared to those with dark brown eyes), there have been no independent scientific studies showing one method is actually superior in practical applications and modern use.

Another form of eye-tracking which has been in many ways superseded by video oculography methods, at least in behavioral studies of individuals with neuropsychiatric disorders, is electrooculography (EOG). Electrooculography uses conductive electrodes placed nasally and temporally to the eye, together with a reference electrode, in order to measure the potential difference between the front of the eye and the back of the eye (the corneofundal potential; see Brown et al. 2006; Marmor and Zrenner 1993). This method of eye-tracking typically is noisier than commercial video oculography systems, and the head must remain relatively immobilized, as compared to video oculography techniques which can accommodate relatively larger amounts of head movements. However, EOG systems are relatively inexpensive compared to VOG eye-tracking systems, making their use a viable alternative in situations where precision is not at a premium and participants are very compliant to instructions and immobilization.

Finally, a form of eye-tracking used primarily in primate and animal research employs scleral coils. With scleral coils, a conducting ring is placed directly on the sclera of the eye and an enclosing alternating magnetic field induced around the head of the participant. As the eye changes position, voltages generated within the coil give the position of the eye, giving extremely precise recordings of eye position. The main drawback of this technique is the physical discomfort associated with inserting the coil directly into the eye and the risk of corneal abrasion. Still, recent work has identified the lead from the coil to the measuring device as a major source of discomfort for scleral coils, and strides have been made using wireless scleral coils which may make the technology more usable for fine-

grained detection of eye movements in the future (Roberts et al. 2008).

Mechanics of Eye Movements and Common Eye-Tracking Outcome Variables

Primary classifications of eye movements include saccades, fixations, and smooth pursuit. Saccades, a term coined by French psychologist Louis Javal in 1879, are rapid, ballistic movements of the eye. Research has shown that awareness of the visual world is suppressed during saccades, an effect neatly summarized by Dodge (1900). Dodge's observation was that when an individual stands in front of a mirror, looking at different positions on his or her own eyes, that individual does not detect any movement of the eyes. However, an observer standing immediately to the side of the person in the mirror will see the eyes moving rapidly. This effect, known as saccadic suppression, is associated with decreased conscious awareness of the visual world during saccades. Fixations are the complement of saccades and represent periods in which the pupil is focused relatively stably and steadily on a particular location. By contrast, smooth pursuits are indicated by slower, sweeping motions of the eye and are found when the eye is used employed to visually track a moving target. Interestingly, smooth pursuits cannot be elicited voluntarily in the absence of a target and require a slow-moving target to manifest.

Fixation/saccade identification algorithms have been advanced in order to segregate saccades from fixations in eye-tracking data. However, it is unclear if these algorithms are effective in drawing clear distinctions between saccades and fixations at modern eye-tracking speeds (60 Hz) and resolutions (Shic et al. 2008a, b). Nevertheless, these fixation identification algorithms are in widespread use and are supported by most eye-tracking manufacturers. By comparison, smooth pursuit recognition, which would affect the interpretation of studies employing dynamic stimuli, is currently not a standard analytical technique.

Perhaps the most common technique used in analysis of eye-tracking data is region-of-interest (ROI) analysis. In ROI analysis, the scene presented to the participant is divided into a series of

not necessarily (but usually) nonoverlapping regions, and the amount of time spent by the participant looking at each of these regions is calculated. As studies of natural activities have shown that people tend to be looking for information they need, it is inferred that more examined areas correspond to areas found by observers to be more important. Typically, for comparability purposes, looking times are expressed as a proportion of the trial time. Some researchers choose to exclude from analyses eye-tracking data acquired during saccades due to diminished awareness of the scene by the participant, but others choose to incorporate all data into proportion data and/or looking time reports.

Additional measures employed in eye-tracking research are extensive (Jacob and Karn 2003), and there exists a large body of research on sophisticated techniques for processing eye-tracking data (see Duchowski 2007; see Holmqvist et al. 2011a for reference). While many of these techniques are theoretically and conceptually interesting, it is also important to note that, in many cases, the relationships between derived eye-tracking variables and physiological or behavioral constructs is unclear. A notable exception is the detection of blinks. The inhibition of blinks has recently been shown to correspond to decreased attribution of salience to social scenes in toddlers with ASD (Shultz et al. 2011). Concerted and rigorous explorations of the space of possible eye-tracking measures may thus more firmly ground our understanding of outcome eye-tracking measures, from psychological, neurophysiological, and behavioral perspectives, in the years to come.

Limitations of Eye-Tracking

Interpretations of the results of eye-tracking experiments often involve assumptions regarding the concurrent relationship between the position of eye and the allocation of attention. However, attention and eye movements are not always coupled; indeed, research suggests that the movement of attention toward a particular point in the world precedes an eye movement toward that location by 100–120 ms. In addition, attention can be moved *covertly*, i.e., without an explicit, overt eye movement. Research has shown,

however, that when a movement of the eye is made, it must be preceded by focal attention to that location. Thus, the occurrence of an eye movement suggests that attention has already been deployed to the target of that eye movement; on the other hand, when the eye is relatively still, standard interpretations of eye-tracking data rely on an assumption that the point of fixation is the same as the point of attention. For practical purposes, this is often the case (Duchowski 2003; Holmqvist et al. 2011; Kowler 1990).

Future Directions

Keith Rayner, one of the pioneers of eye-tracking research, especially in studies of reading, notes that there have been four main eras of eye-tracking research (Rayner 2009). In the first era (early 1900s), many of the basic properties about eye movements were discovered. In the second era (1930s to 1950s), experimental work in eye-tracking research took a behaviorist position, classifying and quantifying, in context, the myriad behaviors comprising eye movements. In the third era (1970s to 1990s), the cognitivist revolution brought new perspectives for delving deeper into the mechanisms and cognitive processes underlying eye movements. Rayner notes that we are now in the fourth era of eye-tracking research, one where quantifiable and predictive models of eye movements, indexing underlying cognitive substrates, can be developed.

While Rayner's summary mainly refers to studies of reading, the same classification of eras can be applied to eye-tracking research in social visual information processing, with the understanding that this field lags research in reading by about a decade. Currently, there is a great deal of interest in using eye-tracking technology for understanding autism, and much of this effort is aimed at understanding the specific individual behavioral and cognitive characteristics that affect visual scanning of social information in autism. Once this heterogeneity of behavior can be decoded, it is hoped that eye-tracking research in autism will also enter into its fourth era, where the accurate models of eye movements can help us

both understand individual variability as well as predict those forms of intervention that will be most efficacious.

The fourth era of eye-tracking research also corresponds with the proliferation and technological development of eye-tracking technology as a whole. In many ways, eye-tracking is now appearing as an almost requisite adjunct methodology for social information processing paradigms that directly target underlying neural substrates, such as functional magnetic resonance imaging and electroencephalography. Combining these multiple sources of information will provide a more complete picture of the multifaceted complexities in ASDs. Given the wealth of information, an increased focus on computational and statistical approaches toward integrating and unifying eye-tracking data with other sources of information will be critical to future research.

Finally, while atypical scanning of social scenes in individuals with ASD has been found by several research groups employing eye-tracking, there is still much work left to do in terms of pinpointing specific behavioral markers of ASD. It is yet unknown whether atypical gaze patterns in ASD are a secondary manifestation of social perceptual disadvantages and to what extent the compounding effects of the atypical experience reflected by these gaze patterns diminish prototypical social development. Current and future work with eye-tracking will thus continue to isolate autism-specific developmental processes and deepen our appreciation of the roles of typical and atypical gaze patterns in shaping the behavioral phenotype of individuals with ASD.

Definition

Facial perception refers to the ability to rapidly recognize and understand information from faces. The ability to perceive faces and to use that information to guide and direct behavior plays a critical role in interpreting and forming representations from the social world and in the acquisition and understanding of reciprocal social interaction. Early facial recognition research suggests that humans innately attend to faces and are able to rapidly recognize faces remarkably early in life (Goren et al. 1975). Within 9 min after birth, infants turn their head to a 90° angle to preferentially attend to faces or face-like images. At 42 min after birth, infants

can imitate facial expressions; and by 2 days old, infants can recognize the face of their mother. One-month-old infants show greater pupillary dilation to faces than to nonsocial stimuli suggesting greater interest and arousal in infants when looking at faces. By the end of the first year of life, infants are able to respond to directional gaze, emotional expression, and facial gestures. These early infant preferential face-directed behaviors mark the beginning of a highly protracted development in which repertoires for the face processing system become more sophisticated over time. The examination of facial perception in typical and atypical development, such as in autism spectrum disorders (ASD), has elucidated face perception processes across behavioral, anatomical, and neurophysiological domains and revealed differences in functioning in individuals with ASD and typical development in face perception.

Historical Background

Research with children with ASD has consistently revealed deficits in facial perception surfacing within the first 3 years of life. Children with ASD show impairments in social behaviors related to the perception and processing of information from faces. These impairments include reduced eye contact, joint attention, and social orienting, deficits in the imitation of faces and in

face recognition, and attenuated responses to emotional displays of others (Dawson et al. 2005).

The retrospective examination of joint attention and gaze monitoring of toddlers through home videos of first birthday parties has provided insight into facial perception in ASD. In novel and uncertain situations, typically developing young children will seek affective cues from others' faces. Given that a child's first birthday can be a highly social, yet novel event, the setting provides the opportunity for a range of observable social behavior. Osterling and Dawson collected videotapes of 1st year birthday parties from children who were later diagnosed with ASD and from children with typical development. The tapes were rated by coders blind to the child's subsequent diagnostic status. The authors found that the children later diagnosed with ASD looked at and attended to faces significantly less than the typically developing children. The authors determined that the single most critical factor in recognizing early signs of ASD was a failure to look at others and attend to faces in a typical manner, at or before 12 months old (1994).

Current Knowledge

The dynamic processes related to facial perception can be examined from behavioral, neuroanatomical, and neurophysiological perspectives. Much of our understanding of facial perception has been derived from clinical work and research with individuals with ASD. These impressions suggest that individuals with autism, compared to typical peers, perform worse on face discrimination, recognition, and memory tasks when behaviorally assessed. Additionally, individuals with ASD display atypical development and anatomical activation of the brain structures involved in face processing and exhibit delayed and differential neurophysiological responses to faces.

Behavioral Perspectives on Face Perception

Very early in life, typically developing individuals show an attentional preference for faces and are equipped for the specialization of face processing.

These specialized abilities involve recognizing upright faces better than inverted faces and interpreting complex interactions such as direction of gaze, emotional expressions, and facial gestures. Into middle childhood, the specialization for facial perception grows in complexity. Typically, individuals show better memory for faces than objects. They also derive meaningful social-emotional information from faces through preferential attention toward the eyes and perceive faces as a holistic unit rather than isolating individual facial features (Joseph and Tanaka 2003). In contrast, individuals with ASD attend to inverted faces for the same amount of time as upright faces and recognize inverted faces better than typical individuals by focusing on isolated features of the face rather than the face as a whole (van der Geest et al. 2002). Further, when viewing faces, individuals with ASD fixate on the mouth region rather than the eyes. Accordingly, they exhibit better performance memory for the lower portion of the face than the upper portion of the face but show a decrease in attention to the entire internal region of the face. As a result, individuals with ASD perform in the below average range on tasks of overall face memory ability. Further, individuals with ASD show impairments in the ability to use information from faces to guide behavior, such as failing to monitor a gaze shift and follow a gaze to share attention.

Studies of facial discrimination and recognition using eye tracking suggest that individuals with ASD employ atypical strategies during facial perception tasks. First, individuals with ASD attend to other objects in the environment more often than the face. For example, a pioneering study using eye tracking found that when watching a videotape of the movie *Who's Afraid of Virginia Woolf*, individuals with ASD attended two times more to the actors' mouth, bodies, and objects in the scenes than to the actors' eyes (Klin et al. 2002). This suggests that individuals with ASD do not seek social information and cues from naturalistic exchanges in the way that typical individuals seek social information. Subsequent studies have shown that individuals with ASD utilize atypical spatial distribution fixation strategies exemplified by fixating to, or avoiding specific

regions of the face, focusing on the mouth, rather than the typical direction toward the eyes.

A second atypical face perception strategy that individuals with ASD appear to use involves processing faces utilizing a piecemeal (i.e., feature-based) strategy (Chawarska and Shic 2009). In contrast, typical individuals employ the piecemeal processing strategy when looking at objects but not faces. Typical individuals attend to faces holistically by utilizing a complex-looking strategy called configural processing (Dawson et al. 2005). Configural processing is the perception and encoding of faces as a single holistic unit by incorporating the major features (i.e., eyes, nose, mouth), in respect to other features throughout the face.

To explore the limitations of the configural strategy employed by the typical population, researchers alter the configuration of faces by inverting and partially obscuring the images.

Typical individuals are adept at distinguishing similarities between faces that are upright; however, when the face is inverted, it is more difficult to discern facial feature differences. Inversion appears to alter the perception of the face by challenging the relational facial features (i.e., eye, nose, mouth), which contests the configural processing looking strategy producing what is called the inversion effect. While inverting faces results in the inversion effect, altering a face by forcing one to focus on individual facial features results in the decomposition effect. Even though typical individuals are adept at perceiving faces, once the face is altered from its original composition (e.g., inverted or presented in sections), the accuracy in which the face is identified is challenged. By challenging the configural processing strategy in these two ways, typical individuals have to abandon a configural processing strategy when looking at faces and adopt a piecemeal strategy as if they were looking at an object. This concept provides support that face perception is a highly specialized and sensitive processing system, which when challenged, forces individuals to compensate using differential processing strategies and neuroanatomical mechanisms that are not specialized for face perception tasks.

From studies exploring the configural processing strategy, the decomposition effect and the inversion effect, researchers have found that typical individuals attend to inverted faces for longer lengths of time, are better at recognizing parts of the face when presented in the context of the entire face, and are better at recognition of the eyes compared to the mouth than their peers with ASD (van der Geest et al. 2002). When presented with the inversion face perception task, individuals with autism spend an equal amount of time looking at upright and inverted faces. This is similar to the way typical individuals attend to upright and inverted objects. By employing the object specific, piecemeal processing strategy, individuals with ASD are better at perceiving specific features of the face or partially exposed sections of the face with emphasis on local detail rather than global detail. In fact, individuals with ASD are in some cases better at feature-based matching, especially around the mouth, because they are not inhibited by the implementation of decomposition effect.

These behavioral-based face perception studies suggest that typically developing individuals use the configural processing strategy to perceive faces and the piecemeal processing to perceive objects while individuals with ASD appear to apply the piecemeal strategy to process both faces and objects. The benefits of configural processing strategies are reflected in better performance on face discrimination and recognition tasks and better memory for faces relative to objects for typical individuals. In contrast, children with ASD perform equally to typical peers and in some cases better on nonface memory recognition tasks that include objects such as buildings, animals, houses, and bicycles (Blair et al. 2002).

Neuroanatomical Perspectives on Face Perception

Much of our understanding of the neuroanatomical structures related to face perception has been driven by research with individuals with impairments in face perception. Studies of the brain in individuals with prosopagnosia, a disorder characterized by intact object recognition ability, but

impairment in the ability to recognize faces, provide a model for face perception that can be applied to ASD. Neuroanatomical findings in individuals with prosopagnosia, who exhibit behavioral face perception impairments similar to those found in ASD, indicate damage to particular cortical regions, such as the fusiform gyrus, indicating a critical role in face perception for this neural region (De Renzi et al. 1994). By utilizing functional magnetic resonance imaging (fMRI), structural magnetic resonance imaging (MRI), and positron-emission tomography (PET), neuroimaging research has provided further evidence that occipitotemporal cortical and other neural structures are functionally abnormal in individuals with ASD during facial perception. The regions identified as playing a primary role in face processing include the fusiform gyrus, the posterior superior temporal sulcus, and the amygdala. This dynamic human face processing system that is linked to the structural encoding of facial features, processing emotional expressions, and interpreting biological movement is critical to understanding the fundamental neural circuitry of the “social brain” (Pelphrey et al. 2007).

Fusiform Gyrus

Research over the last decade has verified a region of the fusiform gyrus that activates more strongly to faces than any other visual stimuli and appears to be specialized for face processing and facial expression discrimination. The fusiform face area (FFA), located in the medial-lateral region of the fusiform gyrus, responds almost twice as strongly to faces than wide varieties of nonface objects (Kanwisher 2000). However, additional research adds complexity to the role of the FFA region. After finding that the FFA is activated while viewing objects that fall in an individual’s area of expertise (e.g., car experts display FFA activation when viewing images of automobiles), Gauthier, Tarr, Anderson, and Skudlarski proposed that the FFA region is not only responsible for face perception but is responsible for the mediation of specific visual expertise. Gauthier and colleagues supported this conclusion by showing that training a group of college students to identify

computer generated 3-D objects (called Greebles) results in an increase of activity of the FFA (1999).

Rather than increased activity in the fusiform gyrus when looking at faces as seen in typical development, neuroimaging findings suggest that individuals with ASD display reduced activation of the fusiform gyrus while looking at faces (Schultz et al. 2000). Further, individuals with ASD exhibit an increase in activation in the inferior temporal gyri, a surrounding anatomical region specialized for object recognition. While for typical individuals, viewing objects of expertise, such as faces, results in FFA activation, individuals with ASD show FFA activation only when looking at images of their specialized interest. While the fusiform gyrus is an area linked to facial perception in typical individuals, for individuals with ASD, this “social brain region” fails to activate to faces in the same manner.

Amygdala

While there is strong research to support the FFA role in the perception of faces, the amygdala plays a significant role in detecting emotional expressions on faces. The amygdala is a fast-responding structure that plays a critical role in notifying other brain regions of emotional arousal through a mediated reward system. This structure quickly and reliably reacts to salient environmental stimuli, especially fear, and plays a role in assigning significance and constructing social judgments, such as inferring personality characteristics from pictures of the face or facial features (LeDoux 1996).

The allure of the amygdala in ASD research was initially recognized in postmortem cases of individuals with ASD who appeared to have limited dendritic tree development resulting in an amygdala that was small and densely packed compared to typical individuals (Bauman and Kemper 1985). Adolphs found that individuals with ASD demonstrated similar impairments to those with focal lesions to limbic structures, including the amygdala. While individuals with ASD are able to form representations of faces and understand basic knowledge of emotions, they are unable to link the perception of faces to social judgments that are often revealed by facial expressions.

Neuroimaging studies of individuals with ASD have reported hypoactivation of the amygdala when viewing images of emotional and mental states of another individual. For example, Pelphrey and colleagues demonstrated that when emotional faces were presented naturalistically through a dynamic video display, all three components of the broader social brain – the amygdala, the superior temporal sulcus, and the fusiform gyrus – were hypoactive (2007). A study examining the perception of emotionally expressive faces in individuals with amygdala and hippocampal lesions found that there was a strong correlation between the extent of amygdala lesions and hypoactivation of the FFA, suggesting that the amygdala plays a direct role on the FFA when interpreting emotionally expressive face (Vuilleumier et al. 2004).

Superior Temporal Sulcus (STS)

The STS region of the brain is responsible for the detection and processing of biological motion (Pelphrey et al. 2007). In synchrony with the amygdala and fusiform gyrus, this neural network is important for linking structural encoding of facial features and emotions to biological motion. Perception of biological motion is thought to underlie impairments in attention and imitation, skills that are strongly linked to language and social development.

Since past research examined the face processing system through the display of emotional expressions using still image stimuli, Pelphrey et al. (2007) were interested in how presenting dynamic facial expressions affects the face processing system. They found that individuals with ASD display reduced activation in the STS, fusiform, and amygdala when faces contain dynamic information, such as movement, relative to static snapshots of the same emotional expressive face. These results were specific to the social brain and were not observed outside of the human face processing system (i.e., STS, fusiform gyrus, and amygdala).

The STS also plays a role in comprehending intentions and detecting “errors” in social situations (Pelphrey et al. 2007). This region modulates tasks involving the attribution of intention

in the context of dynamic social situations. During situations in which an individual’s actions do not fulfill the expectation (e.g., a character in a story is not looking in the direction that the viewer would think he/she should), there was an increase in blood flow to the STS in a typical observer.

However, for individuals with ASD, there was reduced activity in the STS region. The lack of observed activity in the STS during attribution tasks in ASD provides further evidence that the STS region plays a strong role in the social dysfunction in ASD.

Neurophysiological Perspectives on Facial Perception

By utilizing neurophysiological measures such as event-related potentials (ERPs), scientific studies have provided insight into the neuropsychological processes underlying face perception and face perception impairment in ASD. While fMRI studies have allowed researchers to efficiently investigate abnormal regional brain activity during facial performance tasks, electroencephalogram (EEG) and event-related potentials (ERPs) have allowed researchers to examine the temporal characteristics and strength of neural activity by assessing oscillatory activity in response to viewing faces. Unlike fMRIs, which cannot determine the timing of neuronal firing, EEG/ERPs are able to monitor the timing of the summation of a collection of neuronal postsynaptic potentials firing at the resolution of milliseconds. Most studies utilizing EEG data concentrate on the amplitude, scalp topography, and latency. Amplitude is considered a representation of the amount of neuronal resources recruited for a particular process. Scalp topography distribution differences are thought to represent the location of the originally generated neuronal activity, and the timing of information processing speed is represented through the wave-like display of troughs and peaks, known as latency. Because simply passive viewing of stimuli is needed for EEG/ERP studies, valuable information can be gathered from children with significant social communication impairments through the use of EEG/ERP to effectively and noninvasively address fundamental questions

about the neural basis of face processing in individuals with ASD.

Electrophysiology studies are particularly salient in face processing research because of the discovery of a face-sensitive component that occurs with a negative slope at approximately 170 milliseconds poststimuli exposure. The N170 represents one stage in a series of stages of face processing; the P100, a positive going peak around 100 milliseconds, reflects neural activity in basic visual processing; the N170 reflects structural encoding of the face; and the N250 reflects higher order recognition such as affect or identity recognition. The N170 is recorded over the posterior temporal lobe and is greater in the right hemisphere than the left hemisphere. The N170 responds quicker to face and eye stimuli alone, rather than objects or inverted faces. Slight changes in face composition or inversion alter the latency and amplitude of this component. In typical children, the N170 undergoes a prolonged period of development and does not reach full maturation until late adolescence. Between 4 and 15 years of age, the precursor to the N170, identified as the prN170, is measured from the same electrode configuration as the N170 in adults but is more positive (does not extend beyond the baseline) than the fully matured N170 component in adults. The prN170 in children ages 3–6 years is shown to have a faster response to faces. Similar to adults, this component is shown to have preferential responses to faces than objects.

McPartland, Dawson, Webb, and Panagiotides documented the first report of an altered N170 pattern in adolescents and adults with ASD (2004). Individuals with ASD showed a slower latency when looking at faces than furniture and failed to show the face inversion effect. Additionally, researchers observed a slower speed of information processing which disrupts early structural encoding. These differences in the timing of cortical processing suggest that individuals with ASD have abnormal circuitry or delayed neural processes that modulate the face processing system.

Children with ASD also show disruptions to this physiological measure of face processing.

They demonstrate longer prN170 responses to faces than objects. By the age of 6, compared to typically developing peers who continue to show faster responses to faces over objects, children with ASD show no latency differences to faces versus objects (Webb et al. 2006). In addition, research indicates that children with ASD display structural encoding of faces that is disrupted and slowed. While typically developing children exhibit a faster prN170 response to faces than objects, individuals with ASD exhibit a slower prN170 response to faces than objects.

Differential activation patterns have been observed using ERP studies in typical children comparing familiar and unfamiliar stimuli (i.e., caregivers to strangers, familiar objects to unfamiliar objects) as early as 6 months. This suggests early preferential neurological responses to familiar over unfamiliar faces and objects (de Haan and Nelson 1999). Typically developing infants and young children display ERP differences when viewing familiar and unfamiliar faces and objects at the P400 component recorded from posterior electrodes. Children with ASD, however, fail to show a differential P400 component when looking at familiar versus unfamiliar faces. Instead, children with ASD display an enhancement in the P400 component when looking at favorite objects versus unfamiliar objects. These results provide evidence that children with ASD have specific impairment in processing faces, but not objects.

Children with ASD also show abnormal electrophysiological responses when viewing emotional expressions. Compared to typical peers, children with ASD show a slower and more positive N300 wave in response to fear and exhibit abnormal scalp topography. This slower information processing for faces in the N300 for emotional stimuli is associated with greater severity in social domains such as joint attention and social orienting (Dawson et al. 2004).

Neurophysiological studies in early childhood provide insight into the structural and neurological mechanisms that are involved in the development of face processing. Face processing impairments examined at the neurophysiological level provide insight into social brain functioning

and the face processing system in individuals with ASD from infancy and throughout development.

Future Directions

Faces hold special significance and convey valuable social information early in life. Face perception provides a foundation for the development of social cognitive skills such as sharing attention and understanding emotions. Given the prominent role of face perception in social cognition, the study of ASDs has provided insight into the behavioral, neuroanatomical, and neurophysiological components of face perception.

Behavioral studies of face perception in individuals with ASD have yielded insight into visual scanning, face processing strategies, and the role of expertise of processing information. Imaging studies have identified structures related to the processing of faces, such as the fusiform gyrus, superior temporal sulcus, and amygdala, and demonstrated that the structures of the “social brain system” involved in face perception appear to be functioning differently in ASD. Neurophysiological studies have elucidated face-specific brain waves and revealed temporal delays in the processing of faces in ASD.

The ability to process and gather information from facial expressions is crucial for successful social interactions. This unique ability allows humans to understand affective cues in uncertain situations, such as situations that may be dangerous and important for survival, and to accurately read the emotions of another individual. This ability provides attentional and directive focus through gaze monitoring of others and provides a catalyst to overtly and covertly mimic the facial expressions and affective states of others, such as states that offer the opportunity for bonding or shared reciprocal experience (Chawarska and Shic 2009). While face perception provides immediate insight and interpretation of the social world, over time, and development, it is clear that early developing face processing skills set the foundation for the maintenance of exchanges and social relationships.

Definition

A person's face is the source of their identity, a reflection of their internal emotions, and the means by which they communicate thoughts, feelings, and intentions to others. Most people are "expert" face perceivers – able to identify a familiar face, interpret a facial expression, and follow a person's gaze, instantaneously, effortlessly, and without conscious forethought. However, many individuals on the autism spectrum experience

difficulties with face processing and struggle to understand the perceptual and social cues conveyed by the human face.

Current Knowledge

If individuals on the autism spectrum have difficulties recognizing faces and understanding the emotional and social cues in a face, this could contribute to problems in the navigation of everyday interpersonal interactions. In this article, we will discuss the face processing strategies employed by people on autism spectrum and their problems with recognizing face identities and expressions, gaze following, and eye contact. We reason that impairments in face processing abilities have cascading effects on the social and emotional functioning of people on the autism spectrum that further exacerbate their difficulties with social communication and interaction. We propose that the pattern of face impairment in autism is best explained by a failure to attend to the eye information in a face. To account for this eye deficit, we will compare two accounts: the "Eye Avoidance" hypothesis, in which it is proposed that people on the autism spectrum actively avoid the eye region, and the "Eye Indifference" hypothesis, which claims that people on the autism spectrum do not show preferential attention to the socially-relevant information conveyed by the eyes.

Deficits in Facial Identity

The human face is the physical manifestation of one's identity and the primary source of how people individuate one another as conspecifics, each with a distinct personality and personal history. Although it is not a defining characteristic of the disorder, many people on the autism spectrum are impaired in their ability to perceive and recognize facial identity. Research has shown that persons on the autism spectrum have difficulties with the perceptual discrimination of different facial identities (Behrmann et al. 2006; Tantam et al. 1989; Wallace et al. 2008), are impaired in their recognition of familiar faces (Boucher and Lewis 1992), and have problems with learning to

recognize unfamiliar faces (Blair et al. 2002; Boucher and Lewis 1992; Gepner et al. 1996; Hauck et al. 1998; Klin et al. 1999). These impairments do not reflect a breakdown in general perceptual processing, because individuals on the autism spectrum perform equivalently or even sometimes better than control participants on tasks that involve the perception and recognition of nonface objects, such as cars and houses (Wallace et al. 2008; Wolf et al. 2008; Weigelt et al. 2013).

However, not all individuals on the autism spectrum have difficulties with face recognition. In their extensive review of the literature, Weigelt et al. (2012) found that about half of the reviewed studies ($N = 46$) supported differential impaired face processing in autism, whereas the other half ($N = 44$) showed no difference between ASD and non-ASD control groups. Nevertheless, in the studies demonstrating face deficits, systematic breakdowns in face processing were identified. Face deficits in autism are most pronounced when the task involves either immediate or long-term memory for faces. Furthermore, when identifying unfamiliar faces, children on the autism spectrum process eye information differently than typically developing children. On a part/whole task intended to measure holistic strategies, children on the autism spectrum relied less on the eye features than neurotypical children (Wolf et al. 2008). On a series of face matching tasks, participants with autism performed more poorly than neurotypically developing children and children diagnosed with Williams Syndrome on items that tested the upper eye region of the face, but performed on par with comparison groups on items that tested the lower mouth region (Riby et al. 2009). One implication of the converging research evidence is that individuals on the autism spectrum might not have a basic impairment in face recognition, but that they employ face recognition strategies that are different from neurotypical individuals.

Deficits in Emotion

Facial expressions play a key role in our everyday interactions with others because they are our moment-to-moment manifestations of our internal emotions or the emotions that we wish to project

to others (Ekman and Friesen 1971). Therefore, success in social interactions relies on the capacity to recognize and interpret facial emotions in a social context. In typically developing children, the ability to discriminate basic facial expressions, such as anger, fear, sadness, happiness, and surprise, appears by approximately 4 months (Walker-Andrews 1998) and between 8 and 10 months, infants begin to use the emotional expressions of parents or caregivers to form their responses to events in their environment (Camras and Shutter 2010). If individuals on the autism spectrum struggle in their ability to perceive and interpret facial expressions, this would invariably lead to difficulties in everyday social exchanges.

Although there is a clear connection between the accurate recognition of facial expressions and everyday social competence, there is inconsistent empirical evidence concerning whether individuals with autism are differentially impaired in their ability to perceive and interpret facial emotions. On the one hand, there are studies providing results consistent with impaired emotion perception and recognition in autism populations (Corbett et al. 2009; Davies et al. 1994; Loveland et al. 2008; Tantam et al. 1989; Tanaka et al. 2012). Some studies show that individuals on autism spectrum perform worse than control participants on tasks requiring the labeling of primary basic emotions, such as anger, disgust, and sadness (Bölte and Poustka 2003; Boraston et al. 2007). On the other hand, many studies report no differences between typical and autism population participants in their perception and recognition of facial expressions (Baron-Cohen et al. 1997; Castelli 2005; Jones et al. 2011; Lacroix et al. 2009; Ozonoff et al. 1990; Spezio et al. 2007). However, when the expression studies were combined in a recent meta-analysis of 48 papers, Uljarevic and Hamilton (2013) found that people on the autism spectrum performed below control participants, with a calculated mean effect size of 0.80, and an effect size of 0.41 after correction for publication bias. Relative to neurotypical groups, recognition of happiness was only marginally impaired in autism. Individuals on the autism spectrum performed most poorly on their recognition of fear, and the

difference between their recognition of fear and happiness was marginally reliable. The relative sparing of the happy expression and the selective impairment of the fear expression is informative, because whereas the perceptual cues for happiness are centered on the mouth region (i.e., upturned smile), fear requires attention to cues contained in the upper eye region (i.e., widened eye and arched eyebrows) (Dimberg and Petterson 2000; Dimberg and Thunberg 1998; Smith et al. 2005). Thus, evidence from the identity and expression recognition studies suggests that individuals on the autism spectrum might be predisposed to ignore information in the upper eye region.

Cognitive Strategies in Face Processing and Autism

What is the source of the face processing deficits in autism? A likely candidate is the failure to process information in the eye region of the face. The eye region is a perceptually rich area of the face that provides critical cues for recognizing identity (Schyns et al. 2002; Vinette et al. 2004) and expression (Calder and Jansen 2007; Smith et al. 2005). If individuals on the autism spectrum fail to attend to eye information, it follows that they would be impaired in face identity and expression recognition tasks and have difficulty interpreting social cues in their daily lives.

Eye tracking is a powerful technique for revealing cognitive strategies and it provides insights into the perceptual strategies guiding face processing in autism (Black et al. 2017; Boraston and Blakemore 2007). When a photograph of a face is presented to neurotypical participants, the majority of their looking behaviors (70–80%) are devoted to the eye region of the face (Vinette et al. 2004; Walker-Smith et al. 1977). In contrast, when adults on the autism spectrum look at a face, they look less at the eye, nose, and mouth features of the face and more at the external features (hair, chin, clothing) (Pelphrey et al. 2002). Critically, when individuals with autism do attend to the facial features, their gaze patterns are directed more to the mouth area; they spend less time inspecting the eyes (Dalton et al. 2005; Pelphrey et al. 2002; Spezio et al. 2007).

In the real world, faces are not static objects, but are dynamic entities that constantly move and change in reaction to social events in the environment. To capture dynamic social situations, eye movements were recorded while individuals with autism and control participants viewed a film depicting two actors engaged in a highly emotional conversation. Whereas neurotypicals spent the majority of time fixated on the eyes of the actors, individuals on the autism spectrum spent more time looking at the mouths of the actors and unrelated objects in the scene and less time on actors' eyes (Klin et al. 2002). In a replication study, Speer et al. (2007) also found that individuals on the autism spectrum spent significantly less time looking at the eyes than did their typically developing peers. Interestingly, a link was found between social competence as measured by the Social Rating Scale (SRS) and scanning behaviors, such that as social competence decreased, the participant's fixation time on the eyes also decreased. The authors suggested that the amount of time an individual spends fixating on others' eyes in social interactions may reflect the degree to which they are able to interpret social information as conveyed through facial cues.

Developmentally, eye neglect in autism emerges early and provides a reliable predictor of social impairment for toddlers who are later diagnosed with autism (Jones et al. 2008; Klin and Jones 2008). However, the precise age at which these eye contact differences first emerge is unclear. A prospective study using dynamic, but relatively still, face stimuli suggests that infants with autism could be less likely to look at the eyes as early as 3 months of age (Rutherford et al. 2015), but another prospective study using dynamic videos of an individual interacting with viewers found that infants later diagnosed with autism showed normative patterns of eye looking at 2 months of age, with fixation on the eyes declining gradually over subsequent observations (Jones and Klin 2013).

Eye Avoidance or Eye Indifference?

There are two accounts addressing why individuals on the autism spectrum might not show a

preference for the eyes. The “Eye Avoidance” hypothesis asserts that people on the autism spectrum actively divert their attention away from the eyes as a strategy to reduce and regulate social interactions. In contrast, the “Eye Indifference” hypothesis claims that individuals on the autism spectrum are insensitive to the social information conveyed by the eyes, which therefore are perceived to be a region of the face that is not particularly informative, engaging, or adaptively useful. Whereas the “Eye Avoidance” account regards the eyes as aversive and as having a negative valence, the “Eye Indifference” account regards the eyes as a nonthreatening and neutral stimulus. In this section, we will discuss the research relevant to the “Eye Avoidance” and “Eye Indifference” accounts and provide an explanation that attempts to reconcile these perspectives.

Eye Avoidance Hypothesis

Despite the importance of the eyes for recognition of identity and expression, the eyes present the most threatening area of the face to many individuals on the autism spectrum. Eye contact conveys a social message of approach and can be interpreted as an invitation for social engagement and intimacy (Kleinke 1986). In everyday face-to-face encounters, social communication is initiated and regulated through the “language of our eyes.” Therefore, for individuals with autism, avoiding eye contact may be an adaptive strategy for deflecting, discouraging, or coping with stressful social interactions. Indeed, people with autism anecdotally comment that looking into another person’s eyes is an unpleasant, even painful experience (Robison 2007). These anecdotal observations have been validated by the self-reports of older children and adults indicating the threat and anxiety associated with looking at the eyes (Corden et al. 2008; Tottenham et al. 2014).

Physiological measures provide an indirect measure of emotional reactivity. It is well established that increased skin conduction is a measure of increased emotional arousal, and therefore, serves as a good biomarker for examining a possible link between eye gaze and emotion in autism (Bradley et al. 2001). Consistent with an Eye Avoidance account, children with autism

exhibit a higher skin reactivity to direct gaze faces than averted gaze faces, suggesting the direct eye contact is perceived as more threatening by participants. In contrast, the skin reactivity of neurotypical children does not change across direct and averted gaze conditions (Kylliäinen and Hietanen 2006). In an important ecological extension of this finding, Kaartinen et al. (2012) measured the skin conductance response of participants on the autism spectrum and neurotypical control participants using live models. Participants viewed the models displaying either an eyes closed, gaze averted, or direct gaze pose through a liquid crystal shutter. Although no group differences were found in skin reactivity between the participants on the autism spectrum and neurotypical participants, the magnitude of arousal for children on the autism spectrum was reliably associated with their social skill abilities (e.g., language, social communication skills, non-verbal play) in the direct gaze condition, but not in the eyes closed or averted gaze conditions, suggesting that engaging in eye contact promotes social competence. Gaze may interfere with face recognition ability in autism, insofar as skin reactivity to direct gaze faces was negatively correlated with face recognition performance; that is, high skin reactivity to direct gaze faces was correlated with poor recognition (Joseph et al. 2008). Although researchers have not always found a reliable link between skin reactivity and eye gaze in autism (Louwerse et al. 2013), null findings might be related to variations in stimulus type (static, videos, live models), task demands, age, and level of functioning of the participants. As a whole, the bulk of the skin conductance evidence indicates that individuals on the autism spectrum are more emotionally aroused when they look at the eyes of faces and this response is accentuated when the eyes of the faces are looking back at them.

At the neuroanatomical level, a network of cortical and subcortical brain structures that includes the fusiform gyrus, the amygdala, and the superior temporal sulcus is central to social and emotional processing of faces. Whereas the fusiform gyrus is selectively sensitive to faces compared to nonface objects (Kanwisher et al. 1997; Puce et al. 1995)

and to familiar faces compared to unfamiliar faces (Lehmann et al. 2004; Rotshtein et al. 2005), the amygdala is sensitive to emotional information in a face (Kawashima et al. 1999; Morris et al. 2002; Whalen et al. 2004). In autism, activation of amygdala is strongly and positively correlated with the time spent fixating on the eyes, relative to neurotypical participants (Dalton et al. 2005; Hadjikhani et al. 2004; Hadjikhani et al. 2017; Kliemann et al. 2012). Although they are not predisposed to look at the eyes, when individuals on the autism spectrum are cued to the eye region, they demonstrate greater bilateral amygdala activation than neurotypical individuals (Hadjikhani et al. 2004). Tottenham et al. (2014) showed that amygdala activity could be increased through an experimental manipulation to the eyes and that those participants with autism who made the fewest natural eye movements toward the eyes exhibited the highest amygdala response when their gaze was experimentally driven toward the eyes. The researchers hypothesized that those individuals on the autism spectrum who found direct gaze to be the most aversive may have modulated their amygdala-mediated arousal by averting their gaze away from direct eye contact.

For many people on the autism spectrum, looking into the eyes of another person is a threatening experience, one that provokes feelings of anxiety and trepidation. As the foregoing research indicates, subjective feelings of discomfort are manifested in physiological responses that include heightened skin conductance and increased amygdala brain activity and these responses are accentuated by direct eye contact. According to the Eye Avoidance hypothesis, choosing not to look at someone's eyes is an adaptive strategy that allows people on the autism spectrum to regulate their social interactions and manage potential feelings of discomfort that these encounters might elicit.

Gaze Indifference Account

In contrast to the Eye Avoidance hypothesis, the Gaze Indifference hypothesis maintains that individuals on the autism spectrum are insensitive to social cues and, consequently, are indifferent to the role that the eyes play in social

communication. Whereas the Eye Avoidance hypothesis assumes an awareness on the part of people on the autism spectrum to the potential social threat of the eyes, the Gaze Indifference hypothesis claims that they have no awareness of the social meaning or significance of eye information. According to this account, insensitivity to eye gaze is not specific to face processing, but reflects a general lack of interest in the social behaviors of others.

Consistent with the Gaze Indifference account, neuroimaging studies have demonstrated that individuals on the autism spectrum show either hypoactivation or nonselective activation in the amygdala to social stimuli (Pelphrey et al. 2005), to faces (Pierce et al. 2001), and to the eyes (Pelphrey et al. 2005). Thus, in contrast to previously discussed findings (Dalton et al. 2005; Tottenham et al. 2014), these studies indicate that for people on the autism spectrum, the affective valence of a stimulus has little effect on the brain structures that are most closely associated with emotional processing.

To support the Gaze Indifference hypothesis, Moriuchi et al. (2017) monitored the eye movements of 2-year-old toddlers on the autism spectrum while they watched a video of an actress speaking into the camera. When cued to the eyes of the actress, the 2-year-olds with autism did not shift their gaze away from the eyes as predicted by the Eye Avoidance account. Unlike the toddlers from the control group, the eye movements of toddlers on the autism spectrum were unaffected by the social cues of the actress, such as when she made eye contact and spoke directly into the camera. Hence, while the toddlers on the autism spectrum did not find the actress' eyes particularly noxious or aversive, they did not respond to the social cues conveyed through her eyes. The results are consistent with a Gaze Indifference account in which the 2-year-olds on the autism spectrum displayed a passive insensitivity to the social cues conveyed by the eyes of others.

Although the foregoing results are consistent with the Gaze Indifference interpretation, the findings are not necessary incompatible with the Eye Avoidance account. Moriuchi and colleagues

speculated that whether an individual on the autism spectrum responds passively or aversively to the eyes of others might depend on factors related to the age and social and cognitive development of the child. Previous eye gaze reports of atypical amygdala activation (Dalton et al. 2005; Tottenham et al. 2014), heightened anxiety (Corden et al. 2008), and atypical skin reactivity (Kaartinen et al. 2012; Kylliäinen and Hietanen 2006) have examined the responses in older children and adults on the autism spectrum, in contrast to the eye-tracking study by Moriuchi et al., which was conducted with young, 2-year-old toddlers. If children on the autism spectrum learn that attending to the eyes is associated with a potential social threat, then the eye contact-social threat connection would require time, experience, and awareness. The frequency of anxiety symptoms in autism increases with age (van Steensel et al. 2011) and is moderated by cognitive functioning (White et al. 2009). It is not surprising then that the eye contact-social threat contingency is not fully established at 2 years of age. One model proposes that people on the autism spectrum could develop anxiety as a result of stressful experiences, including the stressful experience of navigating unpredictable social interactions (Wood and Gadow 2010). Hence, Eye Avoidance behaviors would not be expected to appear until later childhood and early adulthood, when the connection between social anxiety and eye threat is more firmly established.

Future Directions

Summary

In this article, we discussed the face processing abilities and strategies of individuals on the autism spectrum. Although impairments in the recognition of face identities and expressions are not defining characteristics of the autism spectrum, the converging evidence indicates that many individuals on the autism spectrum have difficulty in these areas. Because their recognition abilities for nonface objects are on par with or superior to those of neurotypical individuals, the deficits cannot be attributed to low-level or perceptual visual impairments but are selective to

face processing. Cognitive and eye-tracking experiments indicate that in contrast to neurotypical individuals, individuals on the autism spectrum fail to attend to and encode the information in the eyes – a region of the face that is critical for recognizing identity and expression.

Two hypotheses have been advanced to explain why individuals on the autism spectrum fail to look at the eyes of another person. According to the “Eye Avoidance” hypothesis, individuals on the autism spectrum divert their attention away from the eyes as a strategy to regulate the social threat of eye contact. In contrast, the “Gaze Indifference” hypothesis posits that individuals on the autism spectrum regard the eyes as a socially neutral stimulus that neither attracts nor repels their attention. Although the autonomic, neuroimaging, and eye-tracking results are inconclusive, it is plausible that the indifference and avoidance responses reflect behaviors at different developmental time points. Gaze indifference behavior might be evident in early childhood (e.g., 2 years of age) when the young child on the autism spectrum is relatively insensitive to the social cues in their world. Eye avoidance behaviors may appear later in childhood (e.g., school age) as a result of increased social interaction and a developing sense of self-awareness. As a test of this developmental account, longitudinal studies could be conducted to monitor for a possible “indifference-to-aversion” shift in eye-tracking behaviors.

If the “eyes are windows into the soul,” then it is little surprise that individuals on the autism spectrum should struggle with understanding the emotions and intentions of other people. Although there might be good reasons why people on the autism spectrum choose not to attend to the eyes of others, understanding the source of this strategy is a rich area for future research and potential interventions.

Definition

Face recognition is an important dimension of face processing in which specific information about identity is derived. The capacity to recognize individual faces is critical to socialization throughout development and adulthood, providing important social cues that guide interactions. While no scientific consensus exists on whether autistic populations show behavioral impairment in the ability to recognize faces, substantial evidence indicates that individuals with autism may use atypical visual and neural mechanisms to determine facial identity. By disrupting the extraction of important social information from the face, these abnormalities in processing facial recognition may contribute to the social deficits that characterize autism spectrum disorders (ASD).

Historical Background

Faces are highly relevant visual stimuli, conveying information critical to social understanding and effective communication. The ability to accurately recognize others' faces, which allows for quick identification of others and retrieval of information associated with them, is particularly critical to social function. Developmental studies indicate that face recognition facilitates engagement with others from infancy; from the first days of life, infants demonstrate the capacity to recognize their mothers' faces among others (Pascalis et al. 1995). Further studies of face recognition ability in children have revealed that the basic capacity to differentiate faces matures over the course of development, following a

developmental trajectory distinct from general pattern recognition or memory (Carey et al. 1980).

Neuropathological findings have emphasized the importance of face recognition over the lifespan, suggesting that circumscribed regions of the brain are specialized for differentiating faces. Patients with prosopagnosia, a disorder of face perception, exhibit normal recognition of common objects in spite of severe impairment in recognizing faces (Whiteley and Warrington 1977), while individuals demonstrating severe impairment in recognizing common objects retain normal face recognition (Moscovitch and Winocur 1997). Together, these findings suggest a double dissociation between face and object recognition, i.e., that face and object recognition rely upon distinct neural networks in the brain. Subsequent neuroimaging studies have indicated that the region of the temporal lobe known as the fusiform gyrus is activated preferentially during face recognition tasks, suggesting the specialization of this brain region for face processing (e.g., Kanwisher et al. 1997). However, recent studies reveal that nonface objects with which an individual has expertise and novel face-like objects also animate this brain region, calling this interpretation into question (Grelotti et al. 2005).

In addition, early research into the effects of inversion upon recognition accuracy has indicated that face and object recognition rely upon distinct processing strategies. Yin (1969) discovered that inversion of faces impairs recognition in typical adults to a greater degree than does inversion of common objects; this robust phenomenon, known as the "inversion effect," suggests that adults use a different visual strategy to identify faces versus objects. Subsequent research indicates that, whereas object recognition depends upon discrimination of individual features, accurate face recognition relies more heavily upon the configuration of the face, which is disrupted during inversion. This processing strategy, however, may not be specific to faces but more generally applied to stimuli that an individual is expert at recognizing; individuals with expertise in nonface objects demonstrate an inversion effect for objects in their domain of expertise comparable to that for faces (Diamond and Carey 1986).

The first experimental investigations of face recognition in autism were carried out by Langdell (1978) to assess whether disruption of the typical visual mechanisms underlying face recognition might contribute to the social impairment observed in children with autism; this research indicated that children and young adults with autism are proficient in recognizing faces but employ atypical visual strategies in order to do so. While children with autism did not exhibit behavioral deficits in recognizing photographs of their peers, they demonstrated a greater reliance on features located in the lower parts of the face (i.e., the mouth region) than did typical peers. In contrast, typically developing children relied more heavily on the upper part of the faces (i.e., the eye region) to recognize peers, replicating previous findings. Langdell (1978) also found that older children with autism failed to show an inversion effect for faces, while typically developing children did. Similarly, Hobson, Ouston, and Lee (Hobson et al. 1988) found that adolescents and young adults with autism were significantly better than typical peers at recognizing inverted faces, which they were able to identify as well as upright faces, suggesting that individuals with autism employ different processing strategies to determine facial identity than do typically developing individuals.

Current Knowledge

Initial studies of face recognition ability in autism indicated that children and adolescents with autism demonstrate behavioral proficiency in recognizing faces but atypical patterns of visual processing. Current research continues to explore the question of whether individuals with autism are impaired in face recognition. However, the focus of this line of investigation has largely shifted from reporting behavioral performance to clarifying the visual mechanisms and neural networks that underlie the distinct processing strategies for face recognition in ASD.

To date, no consensus exists as to whether individuals with autism demonstrate significant deficits in face recognition relative to typically

developing peers matched on cognitive and verbal ability. While several recent studies report behavioral impairment in face recognition in children with ASD that is independent of overall functioning, many have failed to report such impairment (*see* Klin et al. 1999 *for a review*). Although most research to date indicates that recognition deficits in autism are specific to faces, some studies have reported more general impairment in processing both face and nonface stimuli (e.g., Davies et al. 1994). Klin et al. (1999) suggest that these inconsistencies in the literature are attributable to differences in age and functioning in the subject populations, control group criteria, and experimental tasks employed across studies of face recognition in ASD; in addition, Klin et al. (1999) hypothesize that abnormalities in the way facial identity is determined in autism may not always translate into impaired performance because children with autism may develop compensatory strategies for face processing to overcome difficulties in the critical domain of face recognition.

While controversy exists as to whether individuals with autism demonstrate behavioral impairment in the specific domain of face recognition, an emerging body of research supports the hypothesis that atypical visual mechanisms underlie face recognition processing in ASD. Recent studies have provided direct evidence that the facial inversion effect observed in typical adults reflects the use of a configural visual strategy (i.e., one that relies upon the spatial relationship between individual features) for face recognition that is distinct from the feature-based strategies employed in object recognition (Freire et al. 2000). Given the lack of inversion effect in autism, this suggests that facial recognition in autism relies less upon the configural strategies and more upon the feature-based strategies characteristic of object recognition in typical development. However, subsequent work has indicated that high-functioning children with ASD do employ holistic strategies for face recognition (i.e., evaluating the face as a whole rather than part by part) in instances where accurate face recognition depends upon the mouth region of the face (Joseph and Tanaka 2003); this suggests

that atypical patterns of face recognition in autism cannot be fully explained by impairment in configural processing of faces.

Current research confirms that individuals with autism rely upon different regions of the face to determine facial identity. While typically developing children are more proficient in recognizing faces based upon the eyes compared to the mouth, high-functioning children with ASD demonstrate the reverse pattern (Joseph and Tanaka 2003). Eye-tracking studies have provided further evidence that, while observing and encoding faces, individuals with autism may preferentially attend to different face regions than do typically developing peers. Prior research has indicated that adults with high-functioning autism (HFA) spend more time scanning the external features of the face than core internal features (Pelphrey et al. 2002). Similarly, adults with HFA have been found to spend more time viewing mouths, bodies, and objects than eyes while viewing video clips of dynamic social interactions (Klin et al. 2002). In comparison, typically developing subjects spend more time scanning the eye region of faces, indicating that abnormal patterns of viewing faces in autism, characterized by reduced attention to the socially informative eye region of faces and enhanced attention to mouths, may underlie atypical face recognition in ASD (Klin et al. 2002).

Neuroimaging techniques have recently been applied to shed light on the neural mechanisms that support the distinct processing of facial identity in autism. While brain imaging studies of typically developing individuals have consistently revealed activation in the fusiform face area (FFA) to viewing faces (e.g., Kanwisher et al. 1997), individuals with autism demonstrate atypical patterns of neural activation during face processing (Pierce et al. 2001; Schultz et al. 2000). Work in this field has revealed evidence that face processing can occur outside the FFA, at individual-specific sites, in ASD (Pierce et al. 2001). This difference in where face processing occurs in the brain may be associated with distinct strategies for face recognition in this population. Furthermore, individuals with autism and Asperger disorder have shown weak activation

in the FFA and heightened activation of the inferior temporal gyrus during a face discrimination task, the same pattern of brain activity observed when typically developing individuals performed a nonface object discrimination task (Schultz et al. 2000). This supports the idea that individuals with ASD may use feature-based processing strategies to discriminate among both faces and objects, showing a lack of typical specialization of face processing strategies in this population.

Further studies have revealed key differences in how the brain response to faces is mediated in real time in typical and atypical development, suggesting that children with autism show impaired neural processing of faces at multiple stages of face recognition. Two distinct temporal markers of brain activity (the N400 and Pc) have been found to differentiate between familiar and unfamiliar faces and familiar and unfamiliar objects in typically developing 3- and 4-year-olds; in contrast, same-age peers with autism show differentiation between familiar and unfamiliar objects but not between familiar and unfamiliar faces at these two markers, suggesting that impairment in processing facial recognition emerges early in life (Dawson et al. 2002). Disruption of typical mechanisms for discriminating faces at this early age may derail subsequent brain and behavioral development by affecting how children with autism attend to faces in the world around them and how effective they are at gathering critical social information from faces (Dawson et al. 2002). Additional research has revealed that individuals with autism also show significant delay at a key temporal marker of face processing, the N170, compared to typically developing individuals, reflecting slowed neural speed of face processing in autism only 170 ms after viewing a face (McPartland et al. 2004). Slowed speed of processing has been correlated with poorer performance on tests of facial recognition in autism; this suggests that greater delays in neural processing of faces may contribute to difficulties in face discrimination. While the N170 is delayed in typical development to inverted versus upright faces, this inversion effect is not observed in ASD, providing further

support for the idea that individuals with autism may rely upon configural rather than typical holistic strategies for processing faces (McPartland et al. 2004).

Future Directions

While an emerging body of eye-tracking and neuroscientific research has provided evidence that individuals with autism employ atypical visual and neural mechanisms for discriminating faces, the exact nature of the relationship between these divergent mechanisms and social impairment in autism remains unknown. Atypical mechanisms for recognizing faces may serve as both a cause and an effect of social impairment in autism. For example, reduced attention to faces early in development may disrupt typical specialization of visual strategies and neural circuitry for discriminating faces; the resulting abnormalities in processing facial recognition may further deprive individuals of critical social inputs necessary for the development of typical patterns of social behavior (Dawson et al. 2002). Additional work is needed to clarify the connection between divergent patterns of visual and neural processing of facial identity and the social difficulties that characterize autism in order to design effective interventions.

Face Tests

► Facial Recognition Tests

Face Validity

Ellen Johnson
Section of Social Work, Mayo Clinic, Rochester,
MN, USA

Definition

Face validity refers to the extent to which a test appears to measure what it is intended to measure. A test in which most people would agree that the test items appear to measure what the test is intended to measure would have strong face validity. For example, a mathematical test consisting of

problems in which the test taker has to add and subtract numbers may be considered to have strong face validity. The test items appear, at face value, to measure what one is seeking to measure.

Description

A variety of tests have been developed to measure the ability to recognize faces. In order to recognize a face, one must have the basic perceptual ability to distinguish that face from others, often over time and from multiple vantage points. Tests that measure this ability provide information about the accuracy with which the face is represented, recognized, and distinguished from others. A range of skills are critical for face recognition including the ability to analyze the face and its features, understand the relationship of these features within the overall configuration of the face,

perceive the identity of the face across changes in viewpoint and expression, and explicitly recognize the faces of familiar people.

Recognition of faces is critical throughout social development, because faces are used to identify others in social situations more than any other physical characteristic. The face provides a unique way to identify individuals and comes to serve as a representation of that person and their personal characteristics. Infants distinguish faces of familiar individuals shortly after they are born. Without the early ability to recognize and remember faces or to make use of the nonverbal information they contain, many other subsequent learning processes may be derailed, including the development of coordinated eye contact, joint referencing, and emotional reciprocity.

Impaired face recognition in individuals with autism spectrum disorder (ASD) has been demonstrated with a wide range of experimental tests. On average, groups with ASD are less accurate in their ability to recognize the faces of others. This is true for discrimination of facial identities, recognition of familiar faces, and immediate recognition of newly learned faces. Impairment in face recognition appears to be somewhat specific because individuals with ASD are typically unimpaired in their recognition of objects. On an individual level, there appears to be variability in the ability of people with ASD to recognize faces. There is evidence of an association between the degree of severity of face processing impairments and the severity of more general social symptoms. For this reason, tests of facial recognition are important in classifying the degree of difficulty individuals experience in this perceptual domain in clinical and research settings. Standardized face recognition tests are also useful when describing group characteristics of a research sample, because they provide a common means for comparison across studies and for interpreting experimental measures of face processing.

Historical Background

Early reports of individuals who experienced difficulty with recognizing faces were made in the

late 1800s, though these difficulties were usually associated with other visual impairments. Bodamer (1947) coined the term prosopagnosia (i.e., “loss of knowledge of faces”) to describe individuals who had greater impairments with faces than objects. In order to evaluate patients with frank impairments in face recognition, tests of facial recognition were developed. For example, in the 1960s, Benton and Van Allen developed a face-matching test and De Renzi and colleagues developed a same-different face test. The former became the Benton Facial Recognition Test (Benton et al. 1983). Warrington (1984) developed a test that involved learning a set of new faces followed by a series of target-distracter face pairs to test recognition memory for faces, although this measure has not been widely used with autism and nonface information is contained in the pictures that may aid in the discrimination of targets. In more recent years, similar face recognition tests have been included with standardized batteries of memory and neuropsychological functioning. The Wechsler Memory Scales-III (Wechsler 1997) included the Faces subtest, which is appropriate for adults. A very similar task is included in the Children’s Memory Scales (Cohen 1997), and is appropriate for children. Also appropriate for younger children are the Face Recognition subtest of the Kaufman Assessment Battery for Children (K-ABC-2; Kaufman and Kaufman 2004) and the Memory for Faces subtest of the NEPSY-II (Korkman et al. 2007). In recent years, a new set of facial recognition tests has been developed to increase the sensitivity, validity, and reliability of available measures including the Cambridge, Caledonian, Penn, and Philadelphia facial tests. Most of these tests, along with experimental tasks, have been used to assess face recognition in ASD.

The face processing of individuals with ASD has been studied extensively since Langdell (1978) first offered evidence of atypical strategies in the way young children with autism use information to identify familiar faces. Langdell proposed that face processing deficits may explain the social symptoms associated with autism including impaired eye contact and reduced social reciprocity. Throughout the 1980s and 1990s, a

series of studies followed that revealed impaired or unusual patterns of face recognition in children, adolescents, and adults with autism. In many cases, these studies did not use standardized measures of face recognition, and instead used tasks developed for the particular study being conducted.

Most investigations of face recognition have also been limited by small sample size with a few exceptions, thus limiting the ability to generalize conclusions about the integrity of the face recognition system and determine the expected range of function for individuals with ASD. In an effort to address this problem, the Face Recognition subtest of the K-ABC was administered to over 100 children with ICD-10 defined autistic disorder, pervasive developmental disorder-not otherwise specified, and a comparison group without ASD (Klin et al. 1999). Children with autistic disorder (i.e., the most severe cases) recognized fewer faces than the other two groups, even when matched on verbal and nonverbal mental age. Based on this investigation, it was concluded that children with autism exhibited impairments in face recognition that could not be accounted for by more generalized cognitive impairment. Further, this study suggests face recognition difficulty corresponds with autism severity.

Most studies have been also limited by use of a single measure of face processing or recognition. As a result, it has been difficult to compare results across studies, and the ability to determine the nature and relative contribution of various processing deficits is limited. Additionally, while standardized measures provide a means of comparison across studies, they are limited in their sensitivity to the specific challenges with face processing exhibited by some individuals with ASD (i.e., a focus on features within the face rather than the face as a whole, decreased visual attention to the eye region of the face, and reduced disruption in performance when faces are presented upside down). To address these limitations, Tanaka and Schultz developed the *Let’s Face It!* (LFI) Skills Battery of computerized face recognition tasks aimed at children that includes measures of short-term memory, feature processing and configural perception, and holistic processing

of faces. Many LFI tasks require children to recognize and match individual faces across changes in orientation, different emotional expressions, and with certain regions of the face obscured. LFI also includes tasks that measure processing and short-term memory for objects. Compared with a group without ASD, the LFI Skills Battery is sensitive to the specific ASD-related impairments in face memory and matching, a processing advantage for the mouth region of the face, and unimpaired object processing.

Psychometric Data

All tests presented are individually administered, use still photographs of unfamiliar faces, and are thought to measure facial recognition.

The *Benton Test of Facial Recognition* (BTFR; Benton et al. 1983) is a measure of the ability to perceive and match unfamiliar faces without a memory component. Normative samples span a wide range of ages (6–74 years). Black and white photos are presented, with the target at the top of the page and six test faces at the bottom of the page. Photos vary based on orientation and lighting condition across three conditions: (1) an identical photograph, (2) the same face with different lighting, and (3) three-quarter views of the same face. Initially, there is only one target face, but in the latter portion of the task, three of the six faces have the same identity (i.e., there are three correct responses). Administration time typically ranges from 5–15 min, although the items are untimed. The BTFR has a short and long form (i.e., a subset of the first 13 items versus the full set of items). Scores are obtained by a simple summation of correct responses. Normative data is available for 286 adults and 229 children (Benton et al. 1994).

The psychometric properties of the long form are adequate at best, and the short form has poor psychometric properties. In particular, evidence challenging the construct validity comes from work by Duchaine and colleagues who found adults with typical development were able to score in the normal range when administered a version of the BTFR that presented only the

eyebrows and hairline of faces. These authors concluded that the simultaneous presentation of targets and test faces permits the use of feature-based strategies. The same group showed individuals with developmental prosopagnosia could score in the normal range – a challenge to the BTFR's predictive validity.

The *Cambridge Face Memory Test* (CFMT; Duchaine and Nakayama 2006; Bowles et al. 2009) is a standardized assessment of face processing, recognition, and memory of unfamiliar faces with good psychometric properties and sensitivity to face impairments. The CFMT first establishes familiarity with six study images of male faces from three angles (left, frontal, and right) for 3 s each, then tests recognition from multiple viewpoints, different poses and lighting conditions, and with visual noise from a set of forced-choice groupings. Administration lasts between 10–15 min. There are four phases of the task (Practice with Cartoons, Introduction with the Same Images, Novel Images, and Novel Images with Noise). During the Same Images phase, three test items that are identical to the study images are presented for each face. In the Novel Images phase, a brief review of the study images is followed by presentation of 30 test items that vary by lighting or pose. Finally, in the Novel Images with Noise phase, study images are again briefly reviewed followed by 24 test items with different levels of Gaussian noise added to each image. The CFMT also assesses the effect of face inversion, which is thought to disrupt specialized face processing mechanisms. The CFMT is appropriate for adults, and was developed and initially tested with 50 college students and 9 older adults. A long form with 30 additional difficult trials was developed to identify individuals for whom face recognition and memory is a particular strength (Russell et al. 2009). Initial data support the validity of the CFMT, and normative data and reliability measurements are available from 240 healthy adults (Bowles et al. 2009) including measures of acceptable reliability between blocks and good internal consistency based on data from 124 individuals. Of note, normative data demonstrate that norms must be derived from participants with similar race and ethnicity as the stimuli.

A *Cambridge Face Memory Test-Kids* (CFMT-K) has also been developed for children (Croydon et al. 2014). The CFMT-K stimuli are images of children, and it was validated with 401 children between 5 and 12 years of age to demonstrate age-related developmental sensitivity for upright and inverted face recognition and memory.

The *Cambridge Face Perception Test* (CFPT; Duchaine et al. 2007; Russell et al. 2012) does not require face memory. Rather it requires participants to rank order a set of six faces according to their similarity to a target face. There are eight upright trials and eight inverted trials, with 1 min allowed per set. The target face is presented with a three-fourth view and the test faces are morphed to include 88, 76, 64, 52, 40, and 28% of the original target face. Scoring accounts for the magnitude of the error (i.e., distance from correct sort position). Norms are available, but there is significant variability in performance of the initial sample. Adequate internal consistency was reported for a different sample of 126 adults, as well as a high level of correlation with the CFMT suggesting they assess largely overlapping but partially separable abilities (Bowles et al. 2009). Cambridge face measures (CFMT, CFMT-K, CFPT) are available for research.

The *Caledonian face test* (Logan et al. 2016) requires participants to determine the odd-one-out from a group of four faces. That is, they must select the one face that is different from the three distracters. The task is untimed and presented on a computer. Completion time is 3–4 min. Stimuli are synthetic faces with predictable differences between targets and distracters. The face with the mean value across dimensions occurs in every trial and is the target for half of the trials, whereas the other face is selected from a pool of 80 faces, which allows the task to be readministered without learning effects. The difference between faces on each trial has a varying magnitude that is individually controlled for each participant using a QUEST algorithm. The psychometrics of the Caledonian test were determined in a sample of 80 young adults. An inversion effect was present and face discrimination thresholds had comparable sensitivity to

other lab-based measures, both confirmations of the validity of the more efficient Caledonian test. The measure has good sensitivity including detection of individual differences in performance among nonclinical adults. It was also more sensitive to the impairments of an individual with developmental prosopagnosia, with sensitivity almost threefold greater than two other measures of face processing. Finally test-retest on the same day had good reliability. The Caledonian test is available for research.

The *Children's Memory Scales (CMS) Faces subtest* (Cohen 1997) measures face recognition and memory with unfamiliar faces. The test is appropriate for children aged 5–16 years and can be administered in 10 min plus a 25- to 35-min delay. A series of color photographs of unfamiliar faces are presented one at a time for 2 s (either 12 or 16 faces depending on age). Immediately a series of test faces are presented one at a time and the child is asked to respond to each by indicating whether the face was viewed in the learning phase (or not). After a delay, a second series of test images is presented and children are asked to respond in the same manner. Correct responses for the Immediate and Delayed Faces subtests are totaled to attain two scaled scores. Normative data were obtained from a representative sample of children in the United States during the 1990s. Stability of the assessment across administrations is adequate.

The *Glasgow Face Matching Test* (Burton et al. 2010) requires matching in the same view but stimuli are taken with different cameras, which introduce variability in the images, and is particularly relevant in forensic or security identification tasks. The test contains 168 pairs of adult faces with neutral expressions and takes about 15 min to complete. Half the pairs are same-face trials. The test was normed on 300 adults aged 18–80. Split-half reliability is high and performance related to face processing ability on other common manipulations such as recognition memory for faces supports the validity of the test as a measure of face processing ability. A short version with 40 of the most difficult face pairs was also examined using 194 new adult volunteers aged 18–46 and takes about 3–4 min to complete. Short and long versions are available for research.

The *Kaufman Assessment Battery for Children-II (K-ABC-II) Face Recognition Subtest* (Kaufman and Kaufman 2004) is standardized for ages 3–18; however, psychometric data for the Face Recognition test is available only for ages 3–5 years. The test involves viewing and attending one or two photographs of faces with a brief exposure. Then, children are asked to select the correct face or faces from a group. The task requires children to recognize the target face(s) across changes in pose. In the revision of the K-ABC, new items were added to the subtest and distracting features in the background of photos were removed. The K-ABC-II Face Recognition subtest is standardized on a national sample of children and has excellent psychometric properties.

The *Let's Face It! Skills Battery* (Wolfe et al. 2008) is a battery of tasks designed to measure specific aspects of face recognition and memory that are particularly relevant for children with ASD. Administration of the battery occurred over 2 days in the initial validation and requires more time for completion than other individual tests described in this section. The battery contains five facial identity tests, three emotion processing tests, and two object processing tests. Face recognition subtests include: Matching Identity Across Expression, Matching Identity Across Masked Features, Featural and Configural Face Dimensions, Parts/Whole Identity, and Immediate Memory for Faces. The LFI Skills Battery is not standardized, but has been administered to a relatively large sample of children, adolescents, and young adults with ASD (85 total, with >60 responding to any given subtest) and 130 with typical development. The age range of participants with ASD was 5.1–20.1 years (mean age = 11.58) and cognitive functioning was high (mean full scale IQ of 99.74). Effect sizes for individual subtests were moderate to large. The largest effect sizes were found for the Matching Identity across Expression subtest (effect size = 1.00) and for the Immediate Memory for Faces subtest (effect size = 1.00). Moderate effect sizes were also reported for task conditions in which the eye region was tested (Parts/whole identity, Face dimensions).

The *NEPSY-II Memory for Faces Subtest* (Korkman et al. 2007) is thought to measure encoding, discrimination, and recognition of unfamiliar faces. Children are first presented with a series of photos of faces, and the child is asked to identify the gender of each face as a way to increase attention to the stimuli. Immediately after presentation, test trials require children to select the target face from a group of three faces (a target and two distracters). Fifteen to twenty minutes later, children are asked to select the same set of targets from a new set of three faces. The longer delay assesses long-term facial memory. The subtest yields three scores: Memory for Faces Total Score (immediate recognition), Memory for Faces Delayed Total Score (delayed memory for faces), and Memory for Faces vs. Memory for Faces Delayed Contrast Scaled Score (contrast between the first two). The task is standardized for ages 5–16 years. Normative data were collected between 2004 and 2006 from across the United States, and included 1200 children aged 3–16 years. The revision process also included clinical studies of children with ASD. The validity of the subtest is supported by moderate correlations between the Memory and Delayed Memory scores, between the NEPSY-II and NEPSY, between the NEPSY-II Memory for Faces and CMS Faces subtests, and by diminished performance by children with ASD. Concurrent validity data suggest that processing speed and visual discrimination are also involved, and inattention, impulsivity, and repetitive behaviors may influence performance. Internal consistency ranges from adequate to high and has adequate stability over time. Of interest, the NEPSY-II battery also includes other measures of social function including Affect Recognition and Theory of Mind subtests.

The *Penn Computerized Neurocognitive Battery (CNB) Facial Memory Test (FME) and Age Differentiation Test (ADT)* (Moore et al. 2015) are brief web-based computerized measures of functioning validated with functional neuroimaging. Scores for accuracy as well as reaction time for correct responses are available. Good reliability is reported for FME and ADT response speed, adequate reliability for ADT accuracy, and

questionable reliability for FME accuracy. The FME begins with 20 images of faces presented for 1 sec that participants are told they will be asked to remember. Then, a series of 40 test faces is presented including 20 targets and 20 distracters matched on age, ethnicity, and gender. Participants must decide if the face is one that has been viewed previously using a four-point scale (definitely not, probably not, probably yes, or definitely yes). The test takes 4 min to administer. The FME is administered immediately and again after a delay. The ADT takes 3 min to administer and simultaneously presents neutral face pairs; participants must determine which face is older. Stimuli were generated from faces morphed in age in order to control the level of difficulty. The psychometric properties and validity of the CNB have been evaluated with thousands of adults and children in the USA and the Netherlands (Gur et al. 2010; Moore et al. 2015; Swagerman et al. 2016). It is available online for research.

The *Philadelphia Face Perception Battery* (Thomas et al. 2008) measures matching based on similarity, evaluation of attractiveness, gender classification, and identification of older faces. Stimuli were created in software allowing modification of 114 parameters and refined via pilot studies. To develop the tests, 124 adults participated. A target face is presented for matching with two forced choice options in the Similarity test (more/less similar faces) and the Gender test (male/female labels). Two faces are presented with a question for the Beauty test (who is more attractive?) and Age test (who is older?). Test-retest was adequate only for the Similarity subtest based on the performance of 19 participants. A patient with prosopagnosia performed two standard deviations below the healthy adult sample. This test is available for research.

The *Warrington Recognition Memory Test* (Warrington 1984) tests memory of faces after a short delay. It begins by asking participants to view a set of faces and words and judge whether each is pleasant or unpleasant. Then, after a delay, participants must decide which face or word in a target-distracter pair they previously saw. Originally standardized with 300 adults, additional

psychometric testing was conducted with 72 patients with traumatic brain injuries. Internal consistency was adequate; however, as with other face memory tests, the Recognition Memory Test has been criticized because poor performance could be due to general memory impairment.

The *Wechsler Memory Scales-III (WMS-III) Faces subtest* (Wechsler 1997) is a measure of face memory and recognition for use with individuals aged 16–89 years. As with the CMS, this subtest may be administered in 10 min plus the 25- to 35-min delay. Twenty-four photographs of unfamiliar faces are presented one at a time for 2 sec, followed immediately by a test phase of 48 faces. Adults are asked to respond to each item by indicating whether the face was viewed in the learning phase. After a delay, a second test series is presented in the same way. Correct responses for the Immediate and Delayed faces are totaled to arrive at two scaled scores (immediate and delayed). The scales were normed on a representative sample of over 1000 individuals throughout the United States during the 1990s, with good reliability. The Faces subtest was not included in the most recent edition (WMS-IV) of the battery.

Clinical Uses

Measurement of face recognition in a clinical setting may provide useful information about social function as well as memory for social versus nonsocial information. Subtests within larger batteries provide a means for such comparisons and offer standardized scores for comparison with the population. For preschoolers, the K-ABC-II Face Recognition subtest provides a useful measure. Older children may be assessed with tests such as the NEPSY-II Memory for Faces subtest or Children's Memory Scales Faces subtest. The Wechsler Memory Scales-III Faces subtest provides a similar measure for adults. These tests provide a more global assessment of face recognition, but may be influenced by motivation, attention, and repetitive or impulsive responding. As well, they do not provide insight into why face recognition is disrupted. An emerging research

literature with tests such as the *Let's Face It! Skills Battery* and *Cambridge Face Memory Test*, which provide more focused assessment of face recognition and perception, and current psychometric investigations of biological measures of facial recognition, suggests that such tests may ultimately be available.

Facilitated Communication

Maureen Nevers

Center on Disability and Community Inclusion,
Burlington, VT, USA

Definition

Facilitated communication (FC) is an intervention for individuals with a disability that involves pointing to letters or other materials to communicate using the support of a partner. The supporting partner, or facilitator, may provide emotional, physical, or communicative support as needed by the person with a disability (“FC user”) to produce messages. Although FC can be used with different targets, messages are most often generated by typing on a keyboard.

Historical Background

Facilitated communication was first recognized in the 1970s in Australia with the work of Rosemary Crossley. Crossley began to use physical support to help individuals with significant communication and motor impairments to type (Biklen 1990). In 1990 Douglas Biklen published his experience with facilitated communication while at the Dignity through Education and Learning Communication (DEAL) Center in Australia. He shared his changed perspective about the assumptions of the cognitive abilities of individuals with autism and the possibility that their speech challenges were a function of motor expression (Biklen 1990). In 1992 Biklen helped to establish the Facilitation Communication Institute (FCI) at Syracuse University (Syracuse University Institute for Community Inclusion). In the years that followed, FC use expanded, as did the professional community’s concerns about this unproven intervention. In 1992 Cummins et al. published a critical response

to Biklen’s article, challenging many of Biklen’s claims. They concluded their commentary by saying “to imply in the absence of empirical validation that this technique can break through the severe communication difficulties of children with autistic or other severe developmental disabilities raises serious ethical concerns” (Cummins and Prior 1992, p. 240). Even as the use of FC was growing in the 1990s, it continued to be surrounded by controversy related to its validity. Over the next nearly 30 years, numerous studies demonstrated the influence of the facilitator on the messages produced (Hemsley et al. 2018a). Researchers showed again and again that the messages were being authored by facilitator and not the FC user and were therefore denying the person their right to communicate (Hemsley et al. 2018a). By 2020 many professional organizations had officially denounced FC as a valid communication intervention (American Speech-Language-Hearing Association n.d.). FC, or typing to communicate, continues to be supported by the Institute for Community Inclusion (ICI, formerly FCI) and still practiced by some individuals.

Rationale or Underlying Theory

In her 1994 book on facilitated communication, Rosemary Crossley explained that “a partner (facilitator) helps the communication aid user overcome physical problems and develop functional movement patterns” (p. 3).

Goals and Objectives

The training materials associated with FC (Institute for Community Inclusion Training Standards Manual 2000) indicate that the goal of FC is independent typing, which may include speech or reading of the typed message aloud. The Standards state that FC user should be able to demonstrate that they are the source of the typed messages, so that there is no suspicion that it is the facilitator who is influencing the content. Some of the ways described in the Manual include

having the FC user type a message not known to the facilitator or completing some typing tasks independently. The FC user and facilitator are expected to regularly practice activities to build independence. A successful, independent communicator would need to access their communication support, initiate communication, and produce accurate messages without the support of the facilitator (ICITSM 2000).

Treatment Participants

According to information from the Institute for Community Inclusion (ICI) at Syracuse University, people who have significant communication impairment resulting in limited or impaired speech and who are not able to point reliably without support would be potential candidates for FC. The individuals who use this method are referred to as FC user, typer, or communication aid user. Information from the ICI Training Standards Manual (2000) recommends that consideration for the use of FC begin with an assessment which looks at present and past communication, movement, and support strategies. An experienced facilitator trained in assessment would help determine the benefit of FC and possibly develop recommendations for its use (ICI Training Standards 2000).

Treatment Procedures

According to the Institute for Community Inclusion's website entry on supported typing, FC involves the use of a facilitator to help the person with a disability to communicate by pointing at a target. The target can be an object or picture, but most often it is a letter. The letters are accessed from a paper-based or electronic communication display. The ICI Training Standards Manual (ICI) recommends that multiple people be trained as facilitators to increase the validity of the process.

The person who provides the support to the person typing is known as the facilitator. Facilitators are expected to receive training on their role, learning about the specific methods of

assistance that are part of FC. The Institute for Community Inclusion's Training Standards Manual provides the information below regarding the individualized physical, emotional, or communicative support provided by facilitators. The facilitator's physical support is usually provided at the hand, wrist, arm, or shoulder. The facilitator provides resistance, stability, and movement to increase the accuracy of the FC user's point. Emotional support includes encouragement, motivation, and sharing an expectation of competence. It also promotes focus and attention. Communicative support by the facilitator includes monitoring and providing prompts and feedback to make sure the user's selections and message are clear. A wide range of support is acceptable with FC, and ultimately the specific format of assistance is based on the FC user's motor and emotional needs. Depending on the nature and severity of the persons' motor and emotional needs, it may take considerable time for FC to be successful even with the supports described.

Efficacy Information

Questions about the validity of facilitated communication have focused primarily on authorship, determining whether the typed messages are produced by the FC user or if they are a product of the facilitator (Hemsley et al. 2018a). In a review of the FC research, Hemsley et al. (2018a) noted that the primary method for testing the authenticity of the supported typing process is to see if the person typing can share information that is unknown to the facilitator. In 2014 Schlosser et al. published the results of their comprehensive review of peer-reviewed research establishing the source of messages generated through facilitated communication. The review was conducted by a committee of members of the International Society of Augmentative and Alternative Communication (ISAAC) in order to inform the organization's Position Statement on Facilitated Communication (Schlosser et al. 2014).

Relevant materials for the review were initially identified for the use of the term facilitated

communication or equivalent (e.g., supported typing, assisted typing) (Schlosser et al. 2014). Materials were then compared to a checklist of features to identify those that met the committee's established criteria for inclusion in the review. Many of the materials originally identified did not focus on FC or were not published in a peer-reviewed journal and therefore were excluded (Schlosser et al. 2014). In addition, papers needed to include conditions that allowed for the identification of the source of the typed messages. They had to be able to establish authorship of the communication to be included in the review. A total of seven products, both systematic reviews and individual studies, met the checklist criteria and were included in the analysis. Schlosser et al. reported that the results of every one of the reviewed sources established that the facilitator was the source of the typed messages. The messages generated were influenced by the facilitator and did not reflect the communication of the person with a disability. Considered together, the reviewed materials contained strong evidence for the conclusion that the facilitator, and not the FC user, was the author of the messages (Hemsley et al. 2018a). The results of this review were used as the basis of ISAAC's Facilitated Communication Position Statement of 2014. This paper reads "ISAAC does not support FC as a valid form of AAC... The weight of evidence does not support FC and therefore it cannot be recommended for use in clinical practice" (ISAAC 2014, p. 358).

In 2017–2018 the American Speech Language Hearing Association (ASHA) created an Ad Hoc Committee to review the research related to authorship to inform an updated Position Paper on Facilitated Communication. The Committee found that since the work of Schlosser et al. in 2014, no new research had been conducted that included conditions for establishing authorship using facilitated communication (Hemsley et al. 2018a). Schlosser et al. had stated that "Results indicated unequivocal evidence for facilitator control: messages generated through FC are authored by the facilitators rather than the individuals with disabilities. Hence, FC is a technique that has no validity" (Schlosser et al. 2014, p. 2). In 2018 ASHA updated its 1995 Position Paper on

Facilitated Communication to reflect a stronger statement. The 2018 Position Paper ASHA stated:

Facilitated Communication (FC) is a discredited technique that should not be used. There is no scientific evidence of the validity of FC, and there is extensive scientific evidence—produced over several decades and across several countries—that messages are authored by the “facilitator” rather than the person with a disability. (ASHA 2018)

In addition, ASHA's Position Paper (2018) expressed concerns over the use of FC and identified sources of potential harm. When FC is inaccurately used to represent the person's communication they are denied the right to communicate their own thoughts. In addition, focus on FC can reduce the time and financial resources available to pursue other AAC tools and interventions which have been proven effective. ASHA cautions that SLPs have a responsibility to share the issues related to FC and share other AAC options (ASHA 2018).

A number of other professional organizations and advocacy groups have officially denounced the practice of FC based on lack of research to support its claims of authorship. These include American Academy of Pediatrics, American Psychological Association, Association for Behavior Analysis, Association for Science in Autism Treatment, Speech-Language and Audiology Canada, and American Association on Intellectual and Developmental Disabilities (ASHA n.d.)

Outcome Measurement

In the ICI Training Standards Manual (2000), the ICI indicates a range of factors which can affect the FC user's progress toward independence, including those related to the user (e.g., motor skills), the facilitator (their skill, experience, availability), access to the right tools and environments, and practice opportunities.

The ICI Training Standards Manual (2000) offers the following suggestions for documentation as indicators of valid application of FC:

similar patterns of spelling and typographical errors across facilitators; typing of similar topics and

themes across facilitators; consistent style of typing across facilitators; instances of independent and/or initiated communication; self-correction of mistakes; effective use of protest strategies; sharing of information not known to the facilitator; successful participation in message-passing exercises; behavior or actions that confirm typed communication; speech that correlates with typed communication; consistent physical style of typing across facilitators, and physical attention to the typing (e.g., eye contact with the communication device). (p. 13)

Qualifications of Treatment Providers

Facilitators are expected to receive training on the proper way to provide support without influencing the FC user. “All facilitators should participate in a supervised training process so that they learn the appropriate and correct skills for supporting a person in his or her communication” (ICI Training Standards Manual 2000, p. 11). The ICI Training Standards Manual (2000) provides information for facilitators on best practices and methods of moving toward independence.

²Autism Speaks, New York, NY, USA

³Cleveland Clinic Children's, Cleveland, OH, USA

Definition

Factor analysis refers to statistical methods that attempt to represent a set of correlated observed variables (questionnaire items, autism symptoms, etc.) using a smaller number of unobserved (latent) variables, also called factors or dimensions. The ultimate goal of this technique is to determine the number and composition of factors or dimensions that can parsimoniously represent a larger set of variables.

Historical Background

Factor analytic methods began with Charles Spearman's observation that specific measures of children's academic performance and cognitive skills were correlated. He developed a theory that the correlations between different measures of ability were due to a single underlying common factor or dimension that he called "g" or general intelligence (Spearman 1904). Subsequent uses of factor analysis examined whether multiple components of intelligence can be identified, such as verbal and nonverbal abilities. As factor analytic techniques became more popular, their use expanded to other sets of variables, including psychiatric symptoms. Factor analytic studies of psychiatric symptoms have been helpful in identifying the "boundaries" of psychiatric conditions and separating important core markers and components from peripheral or associated symptoms.

One of the earliest uses of factor analysis in autism was a study by Freeman et al. (1980)

examining the factor structure of a behavior observation scale. Since then, numerous studies have used factor analysis methods in samples of individuals with autism. A search of the terms *autism and factor analysis* in PubMed yields more than 800 hits. The majority of studies examine autism and/or other behavioral symptoms, often using specific measures designed to assist in screening, diagnosing, or tracking of symptoms in individuals with autism.

Existing literature suggests that the primary use of factor analysis has been to better understand which autism symptoms group/cluster together to form broader symptom domains. The other major use has been to evaluate how many dimensions are captured by a specific instrument, typically a measure of autism symptoms. Most instruments do not include all autism symptoms or include some items that are not considered core and/or unique aspects of autism (e.g., self-injurious behavior). Thus, results of factor analytic studies examining specific instruments are mainly useful for scoring the instrument rather than understanding the core symptom domains in autism. The exceptions are factor analyses of measures which comprehensively cover autism symptoms, such as the Autism Diagnostic Interview-Revised (Lord et al. 1994).

There are two general categories of factor analyses: exploratory and confirmatory factor analyses. The main difference in these categories is that, in exploratory analyses, variables are used with no preconceived notion or hypothesis of which variables will measure which factor. In confirmatory factor analysis, the researcher specifies, a priori, which variables will measure which factors and whether factors will be correlated. Researchers can be even more specific by explicitly "fixing" how an item or symptom will load on a given factor. Thus, confirmatory methods are more rigorous in that a researcher must have a hypothesis prior to conducting the analysis. Confirmatory methods are also useful in that multiple models that correspond to different hypotheses can be specified and tested. Direct comparisons of the fit of these models to the data provide evidence of the relative plausibility of the hypotheses. However, because not all possible

models can be tested in confirmatory factor analyses, the better fitting model is not viewed as the “truth” but rather a better approximation of reality.

Both exploratory and confirmatory approaches consist of multiple methods for estimating the factor structure, including estimating model fit to the observed variables. Norris and Lecavalier (2010) provide an excellent overview of exploratory factor analytic methods and recommendations for their use in autism and other developmental disorders. Tabachnick and Fidell (2016) provide a very accessible introduction to both exploratory and confirmatory methods. Although principal components analysis (PCA) is not strictly a factor analysis method, results are often highly similar, and this method is included when discussing previous factor analytic studies of autism. Conceptual differences are that PCA involves analyzing all the variance in the indicators whereas factor analysis involves analyzing the common variance (covariance) in the indicators. Differences between the two methodologies are discussed in detail in Tabachnick and Fidell (2016).

Current Knowledge

Defining the Autism Symptom Phenotype

Factor analytic methods have helped to clarify the nature and underlying structure of autism

symptoms. Although there is not perfect agreement across studies, a consensus has emerged as to the number and composition of autism symptom dimensions. Based on accumulating evidence from factor analytic studies (Frazier et al. 2008; Snow et al. 2009; van Lang et al. 2006), the new diagnostic criteria for ASD include two domains (DSM-5) instead of three domains (DSM IV) – a combined social communication domain and a restricted, repetitive behavior domain (American Psychiatric Association 2013). Several investigations have since used factor analytic techniques to evaluate the underlying structure of the new criteria (2-factor model; see Fig. 1). Since these analyses were based on a priori hypotheses, confirmatory factor analysis was used in most studies (Guthrie et al. 2013; Sipes and Matson 2014; Mandy et al. 2012).

Although these types of studies can be informative, results are mostly driven by the samples used; and in the absence of new samples assembled using the DSM-5 criteria, these results need to be interpreted with caution and replicated in future studies. As Kim et al. (2017) note, instead of continuing to debate the optimal number of factors at a given level of the ASD phenotype, perhaps there is value in examining the underlying structural hierarchy in its symptomatology. Such a hierarchical approach would inform our understanding on how features from differing levels (core diagnostic domains, subdomains, related and/or comorbid phenotypes) come together to

Factor Analysis, Fig. 1 Schematic of the ASD factor structure with diagnosis at the top level, followed by the two primary diagnostic symptom domains (as per DSM-5) and subdomains and individual symptoms. Due to the lack

of agreement across studies regarding the exact number and composition of subdomains and symptoms, those are not specified/named in this figure

make up the complex clinical profiles seen in individuals with ASD.

Assessment Tools Used in Autism

As previously noted, factor analysis has also been used in studies evaluating the number and composition of factors/dimensions captured by a specific instrument, typically a measure of autism symptoms (Constantino et al. 2004; Slappendel et al. 2016).

There are hundreds of published studies describing the use of factor analytic methods to evaluate the structure of different tools measuring autism-related constructs. Since this section is not meant to serve as a review of the literature, we highlight here an example of a tool – the Social Responsiveness Scale (SRS) – that has triggered constructive debate among researchers over the past decade or so. Several studies examining the SRS, a quantitative trait measure of autism symptoms, have identified only a single autism symptom factor with predominantly social difficulties represented (Cheon et al. 2016; Constantino et al. 2004; Constantino and Gruber 2005). This discrepancy between a single symptom severity model and the 2-factor model in the DSM-5 (also see Fig. 1) is most likely due to the predominance of social indicators examined on the Social Responsiveness Scale and the focus on population samples rather than mixed clinical or autism-only samples. Specifically, the discrepancy between a single autism factor and separate social communication and restricted/repetitive dimensions is at least partly due to the fact that, in population samples, the majority of healthy individuals will show less variation in symptom levels, while a small minority of mostly affected individuals will show very large variations in symptom levels. This pattern exaggerates correlations among social communication and restricted/repetitive behavior symptoms, resulting in a single symptom severity factor.

In a more recent study of the SRS-2, Frazier et al. (2014) showed that both a two-factor structure (as per DSM-5) and a three-factor structure (DSM-5 but with restricted, repetitive behavior

factor breaking into two factors, insistence on sameness and repetitive mannerisms; see also Georgiades et al. 2007) provided acceptable model fits using confirmatory factor analysis. Of note were the intercorrelations among symptom factors/domains, something that suggests that understanding their co-emergence remains a high priority in conceptualizing common clinical profiles and causal mechanisms underlying ASD (Frazier et al. 2014).

Grouping Variables and Individuals

One of the recent and promising methodological advances in the field has been the use of novel techniques that simultaneously examine categorical and dimensional models of ASD. By using factor mixture modeling, a method that includes factor analysis and latent class analysis, researchers are able to move away from the simplistic debate of “categories versus dimensions” and examine phenotypic models of ASD that integrate the two. By doing so, empirical methods can be used to begin to disentangle the observed heterogeneity in ASD and examine how both, variables and individuals, come together to form more homogeneous dimensions and subgroups within the autism spectrum (Frazier et al. 2010; Georgiades et al. 2013).

Future Directions

In an era where Big Data is becoming more and more prevalent, factor analytic studies may prove to be very useful in “reducing” information without losing the necessary components that can describe the nature and structure of the ASD phenotype. Such an approach, combined with new methods used for the identification of homogeneous subgroups (Frazier et al. 2010; Georgiades et al. 2013) within the spectrum, has the potential to inform the development of more precise diagnostics and interventions.

To truly understand the causes, diagnosis, and prognosis of ASD, prospective factor analytic studies are needed to examine the hierarchical structure of the revised DSM-5 criteria in relation

to time (Georgiades et al. 2017). Such studies can also examine the associations and potential interactions between the core autism domains and symptoms (see Fig. 1) and the “clinical specifiers” (e.g., intellectual and language impairment, comorbid disorders, etc.) introduced in the DSM-5. Factor analytic methods could also be expanded to better understand underlying neurobiological characteristics. For example, different methods may be useful for reducing genetic variants and/or imaging signals variants to a smaller set of dimensions that may correspond with specific symptom and/or behavior profiles.

Future work using factor analyses and related methods would benefit from using empirically supported approaches for determining the number and composition of dimensions. It is clear that a large number of previous studies did not use empirically recommended approaches to conducting analyses. In future work, it will be important that researchers follow general recommendations for implementing both exploratory and confirmatory methods (McCutcheon 2002; Muthén 2001; Norris and Lecavalier 2010; Ruscio et al. 2006).

Factors Affecting Outcome

► Course of Development

Factors Affecting Outcomes

Patricia Howlin and Sarah Savage
Institute of Psychiatry, Psychology and
Neuroscience King’s College, London, UK

Definition

The outcome for individuals with autism is very variable and depends not only on the characteristics of the individual but on many family and environmental factors and external support systems. Childhood factors that are associated with later outcome include early language development, IQ, severity of autism symptoms, and access to appropriate autism-specific intervention. In adolescence and adulthood, the onset of comorbid mental health problems and the lack of adequate support and interventions are associated with poorer outcomes.

Historical Background

It has been evident since the very earliest follow-up studies of Eisenberg (1956), Rutter et al. (1967), Kanner (1973), and others that outcome in autism is highly variable. Many individuals remain highly dependent on support throughout their lives; others are able to live independently and some go on to make significant achievements. Both Asperger (1944) and Kanner (1971) were struck by the wide heterogeneity in outcome among individuals with autism. Kanner (1971), for example, noted that “The results of the follow-up after about 30 years . . . invite serious curiosities about the departures from the initial likeness, ranging all the way from complete deterioration to a combination of occupational adequacy with limited, though superficially smooth social adjustment.” Similarly, Asperger (1944) commented that although the social integration of individuals with autism might be expected to be extremely difficult, if not impossible, this was the case only for a minority and “almost exclusively in

those people with considerable intellectual retardation in addition to autism . . . This is not so with intellectually intact autistic individuals.” Indeed, he suggested that “able autistic individuals can rise to eminent positions and perform with such outstanding success that one may even conclude that *only* such people are capable of certain achievements.”

The factors affecting outcome, and the reasons why some individuals are able to make very good progress while others continue to have significant problems throughout their lives, has been the focus of considerable research over the years.

Current Knowledge

Although many follow-up studies have indicated a relatively poor outcome for individuals with autism, the results of such research cannot be interpreted without detailed information on the characteristics of the individuals involved. Kanner (1943) and Asperger (1944) were among the first to note a possible association between higher intellectual ability and greater achievements in adulthood. Subsequent follow-up studies have confirmed that childhood IQ is highly correlated with adult outcome. For example, in a series of studies conducted in the UK in the late 1960s and early 1970s, Rutter and colleagues (Lockyer and Rutter 1969; Rutter et al. 1967) found that individuals with an IQ below 60 were far more likely to have a “poor” or “very poor” outcome than those with an IQ above 60. Individuals with an IQ of at least 70 (i.e., at the lower end of the normal range) tended to be rated as having a “fair” outcome, while those with a “good outcome” had an average IQ above 80. More recent studies, involving individuals across the IQ range (i.e., from severe cognitive impairment to superior intelligence), have also noted a strong association between IQ and outcome, with very few individuals with a childhood IQ below 75 living independently as adults (see Howlin and Magiati 2017; Magiati et al. 2014; Steinhausen et al. 2016 for reviews). However, childhood IQ alone is not the only factor affecting outcome (Bal et al. 2015; Lord et al. 2015), and many individuals

with a high IQ in childhood still do poorly in adulthood. Thus, it seems that while *only* individuals with a childhood IQ in the average range or above do well in adulthood, even among those with an IQ above 70, outcome can still vary markedly (Steinhausen et al. 2016). The *range* of early cognitive abilities may also be important, in that children who are able to score only on nonverbal tests, or on a very limited range of subtests – even if their scores on these assessments are within the normal range – tend to have a poorer prognosis than those able to score on both verbal and nonverbal tests in early childhood (Howlin et al. 2014).

Another crucial indicator of later outcome is early language development and it is now well established that there is a strong link between early language abilities and subsequent development (Magiati et al. 2014). Thus, the majority of individuals who go on to do well as adults have usually developed at least some useful speech by the age of 5 years. However, there are exceptions to this, and some children with significant early delays in language later catch up and may make good progress more generally. Overall, however, language impairments, particularly if coupled with low IQ, are the factors most strongly associated with a poorer adult outcome. In adulthood, individuals with good verbal comprehension, good spoken language, and a verbal IQ in the normal range are significantly more likely to be functioning well socially than those who are impaired in these areas (Howlin et al. 2014).

There also appears to be an association between the severity of early autistic symptomatology and later outcome, although findings here are inconsistent. Indeed, predicting later adult outcomes from early child characteristics remains highly challenging (Howlin and Magiati 2017; Lord et al. 2015). There is a need to focus more research on different patterns of developmental trajectories in autism, as such knowledge may be important for identifying different genetic aetiologies as well as having implications for more individually tailored interventions (Lord et al. 2015).

Although many follow-up studies suggest that the severity of autistic symptoms tends to reduce

with age, the overall level of autistic symptomatology in adulthood continues to affect social and economic independence (Gillberg et al. 2016; Howlin et al. 2013; Lord et al. 2015). The presence of mental health problems can also have a very negative impact on outcome, as well as proving difficult to treat effectively (Howlin and Magiati 2017). Although estimates of the frequency of mental health problems in autism vary widely, it is estimated that at least half of all individuals with autism suffer from significant emotional and psychiatric difficulties (Croen et al. 2015; Russell et al. 2016; Moss et al. 2015). The most frequent problems relate to stress, anxiety, and depression, but attention deficit disorders and obsessive compulsive disorders are also common. Physical disorders, including epilepsy, are more frequent than in the general population (Croen et al. 2015) and these too can have a negative impact on adult functioning.

Data on the effects of ageing remain limited. Although overall severity of autism symptoms tends to reduce between early childhood and early adulthood, there are few studies of trajectories of change in older individuals. Nevertheless, some small-scale studies suggest that certain cognitive skills (notably visual and working memory) may be less prone to decline in elderly people with autism than in the general population (Lever and Geurts 2016). There is also some indication that quality of life in ASD is less affected by age than in the general population (van Heijst and Geurts 2015), but to date, studies on ageing in ASD are small scale and involve few participants aged over 60.

The role of gender remains uncertain since most follow-up studies have involved so few females. There are some suggestions that women with autism have poorer social outcomes, especially with respect to employment (Taylor et al. 2015) and quality of life (Bishop-Fitzpatrick et al. 2016). However, other studies (Kirby et al. 2016; Woodman et al. 2015) have identified no significant impact of gender.

The role of external, environmental factors on outcome is yet another area in need of much greater research. Although, to date, there is no evidence that early, highly intensive behavioral

or other interventions make a significant difference to functioning in adulthood, it is likely that the quality of early intervention, access to appropriate education programs, and support for families will have an important impact on later life. There are indications, too, that mental health difficulties in adulthood may be associated with environmental disturbance, such as the transition from school, difficulties in coping with college work or employment, family disruption and loss, and change and unpredictability in daily life. The paucity of appropriate adult services, especially for individuals of average IQ, is also likely to be another reason why adults with ASD are more economically, educationally, and socially disadvantaged than adults with other developmental or intellectual disabilities (Roux et al. 2013). Recent studies also suggest the importance of a wide range of other child and adult factors associated with social functioning and autism symptom severity in adulthood. These include bullying, extent of inclusion in school, maternal warmth/quality of mother-child relationships, physical health, independence in daily living skills, executive function, stress, physical health, and adaptive behavior skills (see Howlin and Magiati 2017 for review).

Future Directions

Long-term follow-up studies over the past 50 years have taught us a great deal about the factors that are associated with outcome in adulthood. However, many issues still remain to be resolved. Thus, although there is good evidence that language, IQ, and severity of autism are all linked to longer-term prognosis, we still know relatively little about how these factors interact, or how far environmental, genetic, family, social, educational, racial, or other variables may ameliorate or exacerbate their impact. The role of temperament and personality is almost unexplored, and almost nothing is known about factors that influence functioning in the later years of life.

Research into effective treatments has led to major improvements in early intervention for

many children. However, how long the effects of such interventions endure remains unknown, and much longer-term follow-up studies are needed if we are to judge the true benefit of these (often very costly) programs.

In summary, although research into children with autism has made significant strides forward over recent years, leading to major advances in diagnosis, understanding of causes, and treatment, research into adulthood still has a long way to go. Follow-up studies of individuals identified and fully assessed as children and followed up periodically from decade to decade are essential if we are to understand the factors that influence prognosis and how these factors exert their effects.

Synonyms

Prompt fading; Stimulus fading

Definition

Fading is the process of reducing assistance (i.e., cues, prompts, supports) until no longer needed so that the skill or response being taught is exhibited independently. In behavioral instruction, fading generally refers to *gradually* removing supports put in place during training programs so that the target behavior eventually occurs independently. For example, when teaching a child with autism how to spell his name, the teacher starts with stating each letter out loud and having the child

repeat them until he does so without error. The adult then instructs the child to spell his name and starts by saying only the first letter out loud and then only “mouthing” (silently moving lips) the remaining letters using no voice. Eventually, the teacher asks the child to spell his name, and he does so without additional prompts. The removal of the verbal prompts illustrates the process of fading.

FAFSA

Ernst O. VanBergeijk
Vocational Independence Program, New York
Institute of Technology, Central Islip, NY, USA
Threshold Program, Lesley University,
Cambridge, MA, USA

Synonyms

Financial aid; Grants; Scholarships

Definition

FAFSA is an acronym which stands for Free Application for Federal Student Aid. FAFSA is the mechanism by which the government distributes grants, loans, and student work study funds. More specifically, it is the gateway by which college students and their families access Federal Pell Grants, Stafford and Perkins Loans, Federal Supplemental Education Opportunity Grants, and Federal Work-Study program funds. By completing the FAFSA form, families learn what their expected family contribution (EFC) will be. The EFC is the amount of money the family is expected to contribute to the student's college education. Prior to 2008, only students enrolled full time in a degree-bearing program at an Institution of Higher Education (IHE) were eligible to complete the FAFSA application.

With the passage of the Higher Education Opportunity Act (HEOA) of 2008 (P.L. 110-315), the regulations governing financial aid and the FAFSA process changed to make it easier for students with intellectual disabilities (ID) to gain access to postsecondary education. The term ID is broadly defined and can include students with autism spectrum disorders or cognitive impairments. According to HEOA, a student with an intellectual disability is one who has mental retardation or a significant cognitive impairment *and* is or was eligible for a Free and Appropriate Public Education (FAPE) under the Individuals with Disabilities Education Act (IDEA). This can include students who were homeschooled or attended private schools. The college is responsible for the determination and supporting documentation of the student's ID (Bergeron et al. 2010).

In order for a student with an ID to be eligible, he or she must be enrolled in an approved Comprehensive Transition and Postsecondary Program (CTP). He or she also must meet all of the general student eligibility requirements *except* the following: (1) he or she does *not* have to be enrolled for the purpose of obtaining a degree or certificate; (2) he or she is *not* required to have a high school diploma or have passed an ability-to-benefit test; and (3) he or she must maintain

satisfactory academic progress under school's policy for students in the CTP (Finkel et al. 2010).

After a public commentary period, the US Department of Education began accepting applications from IHE, for approval of their Comprehensive Transition Programs (CTP) in the latter part of 2010. An eligible CTP must be offered by a college that already has an established financial aid program for its general student body. It also must be designed to support students with intellectual disabilities (ID) and include an advising and curriculum structure. The CTP must require students with ID to participate in courses and activities with students without disabilities (Bergeron et al. 2010).

Students with ID will be eligible for Federal Pell Grants, Federal Supplemental Education Opportunity Grants, and Federal Work-Study programs funds only (Finkel et al. 2010). It is important to note that students with ID currently are not eligible for Perkins or Stafford loans.

US DOE-approved CTPs are listed at the National Coordinating Center and include the Consortium for Postsecondary Education for Individuals with Developmental Disabilities and the Center for Postsecondary Education for Individuals with Intellectual Disabilities.

False Positive

Samantha Huestis

Yale Child Study Center, New Haven, CT, USA

Synonyms

Alpha (α) error; Type I error; Wrong decision

Definition

A false positive occurs when the null hypothesis is true and rejected erroneously. That is, a difference is observed when there is no true difference. An individual may be diagnosed with a condition, for example, that he does not have. A test that produces a substantial number of false positives (i.e., Type 1 Errors) is unable to systematically rule out disorders and diagnoses, and consequently has poor specificity.

False-Belief Task

Nirit Bauminger-Zviely

School of Education, Bar-Illan University,
Ramat-Gan, Israel

Definition

False-belief task is based on false-belief understanding which is the understanding that an individual's belief or representation about the world may contrast with reality. False-belief task is a frequently used methodology to examine theory of mind (i.e., child's ability to construct people in terms of internal mental states such as their beliefs, Wellman 1993). It is considered as litmus test of theory of mind, in that in such cases, it becomes possible to distinguish unambiguously between the child's (true) belief and the child's awareness of someone else's different (false) belief (Dennett 1978). First-order false-belief tasks involve attribution about other's false belief with regard to real events; whereas, second-order false-belief tasks are related with what people think about other people's thoughts. In second-order false-belief tasks, the child is required to attribute the false belief of one person based on the thoughts of another (Perner and Wimmer 1985). An example of a commonly used first-order false-belief task is the "Smarties," in which the child is required to predict another child's perception about the content of a box

of candies (that actually includes a pencil) (Gopnik and Astington 1988). A commonly used second-order false-belief task is the Perner and Wimmer (1985) “ice-cream van story” (or John and Marry tasks). In this story, Marry is asked to predict John’s thoughts about the location of the ice-cream man. Only Marry knows the actual location (in the school), but John knows about his former intention to stay in the park. Thus, Marry needs to take into consideration John’s thoughts about the location of the ice-cream man, based on the ice-cream man’s original intentions.

Family Accommodation in Autism Spectrum Disorder

Judah Koller¹ and Eli R. Lebowitz²

¹Seymour Fox School of Education, Clinical Child Psychology, The Hebrew University of Jerusalem, Jerusalem, Israel

²Yale School of Medicine, Child Study Center, Yale University, New Haven, CT, USA

Definition

Ways in which family members, mostly parents, modify their behavior to help a child avoid or

alleviate distress and negative affect associated with mental health problems (Lebowitz and Bloch 2012; Lebowitz et al. 2014).

Historical Background

A sizable body of literature indicates that family accommodation is common among families of children with obsessive-compulsive disorders (OCD) and anxiety disorders. Such accommodation is associated with both proximal and distal negative outcomes. High levels of family accommodation in these populations are associated with increased severity of anxiety or OCD symptoms, poorer psychosocial functioning, and elevated parental distress (Caporino et al. 2012; Lebowitz and Bloch 2012; Lebowitz et al. 2013, 2014; Storch et al. 2007). Additionally, higher levels of family accommodation are predictive of poorer subsequent response to treatment in children with OCD and anxiety disorders (Lebowitz et al. 2016; Kagan et al. 2016). These findings have already yielded clinical benefit through the development of an efficacious parent-based intervention that targets the reduction of family accommodation (Lebowitz et al. *in press*). This work raises the possibility that the study of family accommodation in children with other disorders could yield similar contributions.

Several findings point to a partial phenotypic overlap between autism spectrum disorders (ASD), OCD, and anxiety disorders, in addition to a possible partial overlap in their etiology. The phenotypic overlap exists with regard to the restricted and repetitive behaviors (RRBs) inherent to a diagnosis of ASD. RRBs are defined in the *Diagnostic and Statistical Manual of Mental Disorders 5* (DSM5) (APA 2013) as “restricted, repetitive patterns of behavior, interests, or activities...” Within OCD, compulsions are defined as “repetitive behaviors or mental acts.” While not synonymous, these two concepts bear resemblance to one another (Jacob et al. 2009; Wood and Gadow 2010). In addition to the partial phenotypic overlap, high comorbidity between these diagnostic constructs has been noted, with greater prevalence of anxiety disorders and OCD

in children with ASD than in typically developing children (van Steensel et al. 2011). Children of parents with OCD or ASD are at greater risk of ASD or OCD, respectively (Meier et al. 2015), and the likelihood that an individual will be diagnosed with OCD or anxiety disorders is elevated in relatives of children with ASD (Jacob et al. 2009), pointing to some degree of shared heritability.

Given the above-noted links between OCD, anxiety disorders, and the RRBs of children with ASD, as well as the potential biological links between the disorders, an examination of family accommodation in the context of autism, specifically regarding RRBs, was undertaken.

Current Knowledge

Building on the data related to family accommodation in OCD and anxiety disorders, an examination of family accommodation in the context of RRBs in ASD was deemed worthwhile (Feldman et al. 2019). Applying the concept of accommodation to RRBs, however, is complicated by several factors. Research has suggested the existence of different sub-groups of RRBs, including repetitive motor and sensory behavior, insistence on sameness, ritualistic behavior, compulsive behavior, circumscribed interests, and self-injurious behavior (Honey et al. 2012; Leekam et al. 2011). Notably, different types of RRBs have been linked to different psychiatric symptoms (e.g., anxiety, depression, and oppositional-defiant symptoms; Lidstone et al. 2014; Stratis and Lecavalier 2013). These and other findings (e.g., Leekam et al. 2011) suggest that the various types of RRBs, and perhaps even different specific RRBs within a single sub-group, may differ in both their etiologies and functions.

Furthermore, RRBs may also vary in function and in degree of adaptiveness, indicating that accommodation of these RRBs may be either potentially helpful or detrimental to the child and family system. Certain RRBs may allow the individual to occupy themselves, regulate hyper- or hypo-sensory arousal, or reduce anxiety (Leekam et al. 2011). In some cases, these behaviors can

even provide a source of income and employment (Attwood 2003; Howlin 2003). Other RRBs, however, such as self-injurious behaviors, are unambiguously harmful. Studies link certain types of RRBs, including preoccupation with object parts, sensory interests, and stereotyped motor behaviors, to poorer reasoning skills, lower adaptive functioning at a later age, and increased caregiver stress (Harrop et al. 2016; Troyb et al. 2016). Further complicating the matter, findings suggest that the same RRBs may have differing etiologies and serve different functions for different children (Leekam et al. 2011; Stratis and Lecavalier 2013).

Particularly relevant to the issue of family accommodation in the context of ASD is the role of RRBs in regulating arousal and in alleviating anxiety and distress, similar to the role of compulsive behaviors in OCD (Leekam et al. 2011; Lidstone et al. 2014). It has been proposed that family accommodation of children's OCD symptoms increases the severity of these symptoms over time by enabling avoidance of distress-inducing stimuli and hampering the development of more adaptive strategies for independent regulation of negative arousal (Lebowitz 2013; Storch et al. 2007). To the extent that RRBs might serve to alleviate distress in children with ASD, family accommodation of RRBs may function in a similar manner and could potentially lead to decreased self-regulation.

Prior to Feldman et al. (2019), limited work had been done examining the role of family accommodation in ASD. Russel et al. (2013) examined a small group of adolescents and adults ($n = 23$) with comorbid ASD and OCD who received cognitive behavioral therapy for OCD. In that study, higher reported family accommodation prior to treatment was associated with poorer response to the treatment. Storch et al. (2015) examined the prevalence and correlates of family accommodation of anxiety symptoms in 40 children with ASD and comorbid anxiety disorders. In line with previous findings on family accommodation in anxiety disorders, family accommodation of anxiety symptoms in the context of ASD was found to be highly prevalent and was correlated with the severity of the children's

anxiety symptoms. The same study also found that family accommodation decreased following cognitive behavioral therapy, with the reduction in family accommodation associated with the improvement in the children's anxiety symptoms. Of note, both of the aforementioned studies focused on accommodation of the anxiety or OCD symptoms and did not investigate accommodation of RRBs.

The first study to examine family accommodation of core ASD symptoms, specifically RRBs, piloted the use of the Family Accommodation Scale for Restricted and Repetitive Behaviors (FAS-RRB; Feldman et al. 2019). This study found that accommodation of RRBs is highly prevalent, with 80% of parents engaging in family accommodation at least once a month and 55% reporting daily accommodation. These rates of accommodation are high, but lower than those reported in pediatric OCD (Lebowitz et al. 2016) and anxiety disorders (Lebowitz et al. 2013, 2014, 2016; Thompson-Hollands et al. 2014), as well as those reported for anxiety symptoms in children with ASD (Storch et al. 2015). The most common accommodations of RRBs reported by parents of children with ASD were (1) providing symptom-related items, (2) participating in symptom-related actions, and (3) assisting in the avoidance of symptom-related stimuli. In this study, higher levels of accommodation were strongly associated with higher RRB severity ($r = 0.820, p < 0.001$). Additionally, higher levels of accommodation were associated with poorer communication ($r = -0.258, p = 0.029$) and daily living skills ($r = -0.407, p < 0.001$) in the children, and a majority of parents report feeling distress due to the accommodation. Most parents also reported their children responding aggressively when parents do not accommodate. These findings parallel previous work focused on children with OCD and anxiety disorders (Lebowitz et al. 2013, 2016; Thompson-Hollands et al. 2014).

While certain similarities exist between family accommodation of RRBs in ASD and accommodation of OCD and anxiety disorders, there

are also significant differences. Every child with ASD presents with some RRBs. However, the frequency, severity, and nature of these behaviors vary widely. Some children with ASD experience difficulty primarily in the area of social communication and interaction while presenting with relatively few RRBs. In such cases, parents may have fewer RRBs to accommodate compared with cases in which the RRBs are a more prominent clinical feature. In the context of OCD and anxiety, the accommodation can relate to almost any clinical feature of the disorder. This may partially explain the lower rates of accommodation reported by parents of children with ASD relative to those reported in OCD and anxiety disorders. Additionally, in light of the heterogeneity in form and function of RRBs, it is yet to be determined whether a reduction of accommodation of RRBs would be invariably beneficial or whether clinical recommendations must be informed by a functional assessment of the child's symptoms.

Future Directions

Further research on the directions of associations and the causal links that may exist between accommodation and severity of ASD is required. RRB severity and lower adaptive functioning may lead to increased family accommodation. It is alternatively plausible that, as in OCD and anxiety disorders, family accommodation leads to more severe child symptomatology and to greater functional impairment in the children. A third possibility is that the relationship is bidirectional or moderated by variables not yet taken known. Longitudinal research is critically needed in order to address these questions.

An additional area worthy of attention is the motivation of parents engaging in family accommodation of RRBs. When asked to provide a qualitative description of their child's RRBs, some parents used language expressing a belief that these behaviors were not optional, such as "must" or "have to," in describing both the RRBs

and their own accommodations. As such, parents of children with ASD may be providing accommodations due to their belief that no other alternatives exist. Children's aggressive responses to not being accommodated, reported by a majority of parents, are another likely contributor to the maintenance of such parental accommodations.

Family accommodation may offer a useful target for clinical interventions for individuals with ASD and their parents or families. Future work elucidating the role of accommodation should aim to determine how best to support parents in this context. In both OCD and anxiety disorders, current interventions emphasize the supportive reduction of family accommodation as a path to increasing independent coping in the child (Lebowitz 2015; Kagan et al. 2016; Lebowitz et al. 2018a, b; Salloum et al. 2018). Recent work supports the efficacy of SPACE (Supportive Parenting for Anxious Childhood Emotions), a parent-based intervention that reduces family accommodation of childhood anxiety and OCD. In a recent randomized controlled trial, SPACE was as efficacious as CBT in treating child anxiety disorders, and it led to greater reduction in family accommodation (Lebowitz et al. 2019). A similar approach may be beneficial in cases of ASD. The development and evaluation of such an intervention program targeting the accommodation of RRBs would be novel and could represent an important step forward in autism-specific interventions.

Family Burden

Peter Doehring

Foundations Behavioral Health, Doylestown, PA, USA

ASD Roadmap, Chadds Ford, PA, USA

Definition

The physical, emotional, and economic impact directly associated with the responsibility of caring for a person with ASD, including the secondary impact on all family members. These can include: (a) the economic cost of care (Montes and Halterman 2008), including lost opportunities for income (Jabrink 2007); (b) quality of life (Lee et al. 2008; Khanna et al. 2010); and (c) the impact on siblings (Harris and Glasberg 2003). Unlike the typical costs associated with child rearing, this burden often extends – and may increase – into adulthood, for those families who elect guardianship. It is reasonable to expect that this burden may vary as a function of the family's race, ethnicity, income, and education, given other findings suggesting disparities in accessing health services, and cultural differences in attitudes toward disability. It is generally believed that various types of supports, including parent training, respite care, and wraparound services, can mitigate some aspects of the family burden.

Definition

Family-based treatments attempt to decrease interactions between family members that contribute to psychiatric disorders and to increase interactions that protect them from these problems. The psychoeducational model is most commonly used in conjunction with psychiatric disorders. Family life is all about relationships and communication. Autism spectrum disorders are about communication challenges, misunderstanding of social cues, and lack of emotional understanding, thus affecting relationships in families. The family burden for parents and siblings is very high in families with a member on the spectrum, and the divorce rate is also high in families with children who have autism. In marriage, if one of the partners is on the spectrum, there will be more problems than just the normal marriage conflicts.

Collaborative family work is directed to meet the needs of people with autism and their families and should address problems in each developmental phase of the family life cycle. Parents of a young autistic child are perplexed when they realize that the child is not developing properly and

may feel rejected or unimportant when the child does not seek their attention. Getting a diagnosis and services may be stressful, as well as the process of adaptation: accepting the diagnosis and informing other family members and friends. At school age, the family has to adapt in many ways: confrontation with outside world, dealing with aversive reactions of peers, specific ways of rearing, arranging for child care, and dealing with professionals. In adolescence, families have to cope with the chronicity of the child's disability, with issues of aggression, odd behavior, sexuality, and addiction. Parents have to delay the developmental phase of launching and moving on and are confronted with the perspective of endless care.

Marriages with an autistic member have a serious risk of running into trouble. The spouse with ASD misses relational skills, there will be an asymmetry in the relation, and the non-ASD spouse will feel lonely and neglected.

A diagnosis of an autism spectrum disorder is likely to be experienced as ambiguous loss in a family, because resolution of the situation is not possible and the outcome is not predictable, especially when the individual with ASD may give an outward appearance of health, thus raising too high expectations for his functioning.

Sometimes, families have several autistic members, for instance, one or two siblings, or a father and a son both have the condition, complicating family function and rearing practices even more.

Family interventions have been less effective in reducing core ASD symptoms, yet they do contribute to reducing the comorbid family and behavior problems associated with the disorder in children and adolescents. A biopsychosocial approach with a treatment package (e.g., family treatment, behavioral therapy, and pharmacology) is common in most clinical settings. Some models and schools of family therapy should not be applied in families with an autistic member, because they focus primarily on context, meaning, and mentalizing processes. Moreover, family and couples' therapists should adapt their style, taking into account that family members may have problems with imagination, generalizing, and they need basic knowledge about ASD in order to work effectively with these families.

Historical Background

For decades following Kanner's description of the disorder, it was wrongly believed that the parents, especially the mother, were responsible for causing the disorder by emotional neglect. Family psychoeducation started in the 1970s of last century in the treatment of schizophrenia. It was based on the premise that the patient has a brain disorder and that families need to be supported in their care of the mentally ill person. The emphasis on the biological aspect of the illness is intended to correct that families somehow cause the illness.

Family psychoeducation nowadays is commonly used in various chronic childhood and adult illnesses.

Current Knowledge

Nowadays, the association of genetic factors in the etiology of autism spectrum disorders is well established. Problems in parenting and family dysfunction may be a response to the child and adolescent psychopathology. A psychoeducational approach in families is the treatment of choice in clinical practice. It is defined as the systematic administration of information to both patient and family (significant others) about symptoms, diagnosis, treatment, and prognosis. Its aim is behavioral change and not just teaching for the sake of increasing knowledge. It must be given in doses, as the recipients are able to hear it and given repetitively over time. Other goals are improving family skills, positive communication development, and increased social involvement for the family. Family psychoeducation includes the provision of emotional support and resources during periods of transition and crisis.

Future Directions

Early diagnosis and treatment of the child and its family may have positive effects for some children. There is no cure for ASD, yet various treatments are used to treat the effects of the disorder.

Family-Centered Care, Second Edition

Laura Foran Lewis
College of Nursing and Health Sciences,
University of Vermont, Burlington, VT, USA

Synonyms

Family-centered practice; Patient- and family-centered care

Definition

Family-centered care is an approach to care that is based on the understanding that the family is a child's primary source of strength and support (American Academy of Pediatrics 2012). As such, the family is recognized as an integral part of the team in collaboration with service providers to best support the care of the child. Service providers view the family as a unit that includes the child, and this unit is the primary focus of care (Coyne et al. 2018). The family unit may include parents, extended family, and/or other caregivers who are determined to be most meaningful and supportive to the child in time of need (Baas 2012).

Core attributes of family-centered care include collaboration, evidenced by empowering families to participate in care by building partnerships that provide dignity and respect; communication, evidenced by honest and open information-sharing, providing choices, and including families in shared decision-making; negotiation, evidenced by educating and building family confidence in care, sharing expectations of roles and responsibilities with family, and assessing families' needs to provide care that is holistic and individualized; and support, evidenced by providing care that is appropriate to the cultural and social context of the family, including formal and informal support (Coyne et al. 2018).

Family-centered care is mutually beneficial for the child, family, and service providers. Research

has shown that family-centered care leads to improved health outcomes, decreased health-care costs, more effective allocation of resources, and increased child, family, and staff satisfaction (American Academy of Pediatrics 2012). Youth on the autism spectrum who receive family-centered care are also more likely to experience successful transition from pediatric to adult primary care (Rast et al. 2018). Families experience increased coping, adjustment, confidence, and competence as caregivers and decision-makers when family-centered care is utilized. Inclusion of the child as developmentally appropriate encourages the child to take responsibility for his or her own health and assist with transition to adult services (American Academy of Pediatrics 2012; Christon and Myers 2015).

In the care of children on the autism spectrum, families are constant in the child's life and therefore can provide a unique perspective and information to service providers who transition in and out of a child's life when planning, delivering, and evaluating interventions. Including families in creating goals of care and incorporating family-centeredness throughout care is a particularly effective tool in managing medical concerns for children on the autism spectrum.

Synonyms

[Febrile seizures](#)

Definition

Febrile convulsions are a common type of seizure seen in children between the ages of 6 months and 6 years. These seizures are triggered by fever, (temperature > 38 °C) but with no evidence of encephalitis or meningitis or prior history of afebrile seizures. Children who have febrile seizures typically have an acute intercurrent viral or bacterial illness such as an ear infection or sinus infection. The seizures are not associated with any systemic metabolic abnormalities such as hypoglycemia.

Febrile seizures are commonly categorized as simple or complex. Simple febrile seizures last less than 15 min (typically only last a minute or two) and have no focal features. Two or more simple febrile seizures can occur in succession, but the total duration of the seizures should be less than 30 min. A “complex” febrile seizure is one that has focal features, may last more than 15 min, or, when they occur in a series, may last more than 30 min. Rarely, febrile seizures can present with status epilepticus.

Febrile seizures are a type of “provoked seizure.” Seizures can also be “provoked” or “triggered” by head injury or withdrawal from medications.

Federal Rules of Evidence

Edward McNulty
Quinnipiac University School of Law, Hamden,
CT, USA

Definition

In General

The Federal Rules of Evidence are the rules governing the admissibility of evidence at civil

and criminal trials in federal courts. The Federal Rules of Evidence generally comprise a set of restraints that the courts place on lawyers in an attempt to manage the risks associated with the adversarial process in a trial setting. The Federal Rules of Evidence were adopted in 1975, and as of 2009, 42 states had adopted codes based on the federal model.

Admission of Relevant Evidence

Federal Rule of Evidence 402 provides for the admissibility of relevant evidence unless the rule provides otherwise. Federal Rule of Evidence 403 gives the trial judge discretion to exclude relevant evidence where its probative value is substantially outweighed by the danger of unfair prejudice, confusion of the issues, or misleading the jury, or by considerations of undue delay, waste of time, or needless presentation of cumulative evidence. Because exclusion occurs only where the probative value is “substantially outweighed,” the rule favors admissibility.

Witness

Federal Rule of Evidence 601 serves the purpose of removing a considerable number of the common law grounds for disqualifying witnesses. In particular, a section of Federal Rule of Evidence 601 states that “[e]very person is competent to be a witness except as otherwise provided in these rules.” Federal Rule of Evidence 602 requires that before a witness can testify, evidence must support that the witness has personal knowledge and memory of the matter. Thus, one may not testify to knowledge obtained from what others told them.

Expert Witnesses

Under Federal Rule of Evidence 702, only experts may testify on matters that are scientific, technical, or specialized in nature. In *Daubert v. Merrell Down Pharmaceuticals*, the Supreme Court held that (1) “general acceptance” is not necessary precondition to admissibility of scientific evidence under Federal Rule of Evidence and (2) under the Federal Rules of Evidence, the trial judge is assigned the task of ensuring that any and all scientific testimony or evidence admitted is not only relevant but reliable. In *Daubert* and similar

cases, the United States Supreme Court set forth a number of factors to consider in determining whether to admit expert testimony under Federal Rule of Evidence 702. These factors are neither exclusive nor dispositive. For instance, the US Supreme Court stated in *Daubert* that courts may consider whether the theory or technique employed by the expert is generally accepted in the scientific community, whether it has been subjected to peer review and publication, whether it can be and has been tested, whether the known or potential rate of error is acceptable, and the existence and maintenance of standards and controls.

Sources

Daubert v. Merrell Dow Pharmaceuticals, Inc., 509 U.S. 579 (1993).

Federal Rules of Evidence (As amended to December 1, 2011)

Federal Rule of Evidence 402. General Admissibility of Relevant Evidence

Relevant evidence is admissible unless any of the following provides otherwise

- the United States Constitution
- a federal statute
- these rules; or
- other rules
- prescribed by the Supreme Court.

Federal Rule of Evidence 403. Excluding Relevant Evidence for Prejudice, Confusion, Waste of Time, or Other Reasons

The court may exclude relevant evidence if its probative value is substantially outweighed by the danger of one or more of the following: unfair prejudice, confusing the issues, misleading the jury, undue delay, wasting time, or needlessly presenting of cumulative evidence.

Federal Rule of Evidence 601. Competency to Testify in General

Every person is competent to be a witness unless these rules provide otherwise. But in a civil case, state law governs the witness's competency regarding a claim or defense for which state law supplies the rule of decision.

Federal Rule of Evidence 602. Need for Personal Knowledge

A witness may testify to a matter only if evidence is introduced sufficient to support a finding that the witness has personal knowledge of the matter. Evidence to prove personal knowledge may, consist of the witness' own testimony. This rules does not apply to a witness's expert testimony under rule 703

Federal Rule of Evidence 702. Testimony by Expert Witnesses

A witness who is qualified as an expert by knowledge, skill, experience, training, or education may testify in the form of an opinion or otherwise, if: (a) the expert's scientific, technical, or other specialized knowledge will help the trier of fact to understand the evidence or to determine a fact in issue (b) the testimony is based on sufficient facts or data; (c) the testimony is the product of reliable principles and methods; and (d) the expert has reasonably applied the principles and methods to the facts of the case.

Feedback-Related Negativity

Michael J. Crowley
Developmental Electrophysiology Laboratory,
Yale Child Study Center, New Haven, CT, USA

Synonyms

[Feedback error-related negativity \(fERN\)](#); [Medial frontal negativity \(MFN\)](#)

Definition

The feedback-related negativity or FRN is an electrical brain signal measured with an electroencephalogram. Detectable at the scalp via the event-related potential (ERP), the FRN occurs when an individual receives external feedback (visual, auditory) indicating that performance is worse than expected in a given context. Such contexts include monetary loss and feedback about performance in simple games. The FRN occurs approximately 250 ms after feedback and is typically observed at central to frontal-central scalp regions. The most likely neural generator of the FRN is the anterior cingulate cortex (Gehring and Willoughby 2002; Luu et al. 2003).

Feeding Disorder

- [Pica](#)

Feeding Problems

Allison Bean Ellawadi

Speech and Hearing Science, The Ohio State University, Columbus, OH, USA

Definition

Feeding problems are delays and/or disorders in the development of eating and drinking skills including disordered placement of food in the mouth, difficulty in appropriately manipulating food when it is in the mouth, difficulty chewing, and/or difficulty swallowing (American Speech-Language-Hearing Association 2001). Feeding problems also include deficits in “any aspect of taking nutritional elements that result in under nutrition, poor growth or stressful mealtimes for children and their caregivers”.

Historical Background

In the early 1900s, doctors were cognizant of the fact that behaviors such as vomiting could be a symptom of feeding problems including overfeeding or too frequent feeding, medical conditions such as pyloric obstruction, and feeding of improper foods (Lowenburg 1912). By 1935, clinicians were addressing feeding problems that occurred as the result of structural anomalies with equipment such as the modified Asepto syringe and medicine dropper. In fact, the Brecht feeder was specifically developed to assist in feeding infants with structural abnormalities and/or physical and mental handicaps (Hess 1946). Feeding problems began to appear in physicians' descriptions of developmental disabilities, such as cerebral palsy in the 1950s (Ingram 1954; Perlstein and Barnett 1952). During this time, it was suggested that feeding problems be classified into one of two groups: organic feeding problems and feeding problems in children who are emotionally disturbed and show tension and anxiety (Shwartz 1958).

By the 1970s, reports suggested that feeding problems occurred frequently in preschool

handicapped children and were a “significant clinical entity” (Palmer et al. 1975). However, no system was consistently being used to classify these difficulties; a problem that continues to exist today. Feeding problems during this time were attributed to neuromotor dysfunction or physical abnormalities. In cases where neuromotor dysfunction and physical abnormalities were ruled out, the feeding problems were determined to have a behavioral cause (Thompson and Palmer 1974). Interventions to address feeding problems included techniques designed to treat feeding problems caused by mechanical difficulties (as cited by Thompson & Palmer). These techniques often included positioning recommendations aimed at facilitating movement and/or prescribed exercises to normalize tone and oral sensitivity. Treatment of behavioral feeding problems often included psychotherapy, using hunger as a means to motivate the child to eat a specific food and gradually increasing texture as a means to introduce solid foods into a child's diet, and/or behavioral modification strategies (Benotvin 1970; Bernal 1972; Jones 1982; Thompson and Palmer 1974; Palmer et al. 1975).

Diagnosis and treatment of feeding problems is still in its infancy. The treatment strategies used during the 1960s and 1970s are similar to those used now (for a review of early strategies, see Palmer et al. 1975). One of the most significant changes in treatment of feeding problems since the 1970s is awareness that feeding is a give-and-take experience that relies on both the child and caregiver. Thus, treatment today often includes consideration of child-caregiver interactions during mealtimes.

Current Knowledge

Successful feeding involves (1) acceptance of a wide variety of developmentally appropriate foods and (2) development of motor skills that enable efficient and safe sucking, chewing, propelling, and swallowing. However, normal feeding development is not restricted to the physical act of eating. It also includes the successful integration of a range of physical functions and interpersonal relationships. Both physical factors

(e.g., integration of swallowing and respiration, hand-eye coordination, normal posture, and tone development) and social factors (e.g., cultural patterns and social factors within a family) influence feeding development (Arvedson and Brodsky 2002). Disruption in one or more of these areas can result in a feeding problem (Bryant-Waugh et al. 2010).

Feeding problems are defined as delays and/or disorders in the development of eating and drinking skills. This includes the motor aspects of eating (e.g., difficulty chewing and difficulty swallowing) as well as deficits in taking nutritional elements, which causes poor growth or stressful mealtimes (American Speech-Language-Hearing Association 2001). Feeding problems manifest themselves in a variety of ways, ranging from an inability to swallow without choking to restricted diets. Approximately 25–40% of infants and toddlers are reported to have feeding problems (Reau et al. 1996). Many early feeding problems are transient and resolve without significant clinical intervention (Bryant-Waugh et al. 2010). However, others fail to resolve without intervention. These feeding disorders often have multifactorial causes, which may include structural abnormalities, and a substantial behavioral component (Arvedson and Brodsky 2002; Bernard-Bonnin 2006).

A consistent classification system is not yet used for feeding problems. The Diagnostic and Statistical Manual of Mental Disorder-4th Edition (DSM-IV) classifies feeding disorders into three diagnostic categories: feeding disorders, pica, and rumination disorders. However, a number of eating disorders commonly seen in early childhood have no place in the DSM-IV classification system (Bryant-Waugh et al. 2010). The organic and nonorganic dichotomy has also been used to classify feeding problems. Organic feeding problems occur as a result of structural anomalies, neuromuscular issues, or other known physiological causes (e.g., gastroesophageal reflux), whereas nonorganic feeding problems occur due to disruptive environments or have emotional underpinnings. While this dichotomy is helpful, feeding problems often have more than one cause (for a review, see Burklow et al. 1998). The American Speech-Language-Hearing Association has

adopted a more in-depth classification system (American Speech-Language-Hearing Association 2007). While this classification may prove to be more useful than the organic/nonorganic dichotomy, it does not address the issue that most children with feeding problems often have multiple diagnoses (Arvedson and Brodsky 2002) and, as such, may fall under more than one category. For example, organic factors may disrupt the typical development of eating which results in the development of maladaptive behavioral patterns by the child and/or the caregiver (Burklow et al. 1998).

Given the complexity of many feeding problems, an interdisciplinary approach to addressing these problems is recommended. Interdisciplinary feeding teams may include a speech-language pathologists, developmental pediatrician, otolaryngologist, gastroenterologist, nutritionist/dietitian, occupational therapist, and social worker or nurse. Speech-language pathologists conduct feeding and swallowing evaluations and develop feeding plans. Developmental pediatricians provide diagnoses of pediatric and neurodevelopmental disabilities and manage overall patient care. Otolaryngologists examine the integrity of the structural mechanisms of swallowing and manage medical and surgical treatment of issues related to drooling, aspiration, and gastroesophageal reflux. Gastroenterologists conduct gastrointestinal evaluations and manage gastrointestinal diseases. The nutritionist/dietitian assesses and manages the child's nutritional needs, and the occupational therapist evaluates the child's posture, tone, and sensory system. Social workers or nurses coordinate home care and other appointments (Arvedson and Brodsky 2002).

Regardless of who is on the team, diagnosis and management of feeding problems follow the same steps: (1) define the feeding and/or swallowing problem, (2) identify etiology(ies), (3) determine appropriate diagnostic tests, (4) plan approach to patient/family, (5) teach about problem, (6) implement treatment, monitor progress, and (7) evaluate progress (Arvedson and Brodsky 2002). Determining the underlying etiology is a critical aspect of any successful intervention program because disturbances in feeding and eating behavior with similar clinical presentations

may differ in their underlying etiologies and require different interventions (Bryant-Waugh et al. 2010). Certain medical conditions and developmental disabilities are associated with specific feeding problems. Neurological conditions and anatomical anomalies are most often associated with skills deficits such as oral motor delays, whereas medical conditions such as gastroesophageal reflux are most often associated with food refusal among children with Down syndrome, autism, and cerebral palsy (Field et al. 2003; Williams et al. 2005).

Feeding programs often have multiple components. For example, programs may address oral sensorimotor issues and posture and positioning during feeding. Oral sensorimotor programs are designed to address deficits in the structures that support feeding and swallowing. Goals of these programs may include improving jaw, lip, and/or tongue movements; developing coordinated movements of the mouth; and normalizing sensory oral experiences during mealtimes. Therapy may also be aimed at developing transitional feeding skills including spoon-feeding, cup-drinking, straw-drinking, and chewing. In addition to targeting skills that directly support feeding, interventionists may also address positioning and posture. Positioning is especially important for children with abnormal muscle tone. Management of behavioral feeding problems may focus on weight gain, initiation of oral feedings, weaning from tube feeds, increased oral intake, improved cooperation and reduced stress during mealtimes, and/or acceptance of a wider variety of flavors and textures (Arvedson and Brodsky 2002). Because mealtimes offer the opportunity for parent-child interactions, it is important that management of feeding and swallowing problems occurs within the context of social and communicative activities associated with mealtime for a parent and child (Arvedson and Brodsky 2002).

Future Directions

The field of feeding problems is still in its infancy, especially with regard to feeding and swallowing

problems in children (Arvedson and Brodsky 2002). Although research in the area of feeding and typical swallowing and swallowing disorders has increased, continued research is needed. In the field of feeding problems, there are still inconsistencies in terminology and the detail of description of a number of eating problems, which hampers research. Thus, it is critical that an internationally recognized and accepted classification is established to inform clinical interventions for particular disorders and move the field forward (Bryant-Waugh et al. 2010).

To date, few research studies have attempted to examine prognosis, course, outcome, and treatment response in feeding disorders using a formal, widely accepted classification system. There is little evidence to guide clinical determination of what constitutes a clinically significant feeding problem and to help clinicians distinguish feeding problems that are more serious from those that are likely to be short lived. In order to better assess prognosis and outcome, researchers should employ a set of consistently used standardized assessment measures (Bryant-Waugh et al. 2010). In addition to directly examining feeding problems, research should continue to examine the outcomes of feeding assessment and intervention in schools and the overall impact on education. Finally, there needs to be an expansion of education programs focused on delivery of feeding and swallowing services in the school (American Speech-Language-Hearing Association 2007).

Feingold Diet

Susan Hyman

Developmental and Behavioral Pediatrics,
Division Chief Neurodevelopmental and
Behavioral Pediatrics, University of Rochester
Golisano Children's Hospital,
Rochester, NY, USA

Definition

Feingold diet is a dietary intervention popularized for symptoms of inattention, impulsivity, and hyperactivity by Benjamin Feingold, M.D., a pediatric allergist who clinically observed improvement in behavior in his patients for whom he prescribed dietary restrictions for management of symptoms of allergy in the 1960s. It calls for the elimination of synthetic food colorings and synthetic preservatives made from petroleum-based products, synthetic sweeteners, and foods containing high levels of natural salicylates (related to the chemical compound in aspirin).

The Feingold diet eliminates:

- Synthetic food coloring made from petroleum products (e.g., Red #40; Yellow #5)
- Synthetic food preservatives made from petroleum products (e.g., BHT-butylated hydroxytoluene)
- Foods that may be high in natural salicylates (e.g., apples, almonds, berries, cucumbers, grapes, and oranges, among other fruits and vegetables)
- Artificial sweeteners (e.g., aspartame)

Foods could be reintroduced as tolerated. Later modifications to the diet included removal of the preservatives Sodium Benzoate and BHA (butylated hydroxyanisole).

While other dietary approaches to hyperactivity have become popular since the initial dissemination of the Feingold diet, the additional assertions that sugar, yeast, milk, or other foods result in behavioral change were not part of the Feingold diet.

Historical Background

It was initially reported in the 1940s that some foods high in natural salicylates and FD and C Yellow #5 (a food coloring approved for food, drug, and cosmetics) produced similar allergic symptoms. Dr. Feingold was the chief of pediatrics of Cedar Sinai Medical Center in Los Angeles and subsequently the Chief of Allergy for Kaiser Permanente Medical Center in San Francisco. In 1965, Dr. Feingold prescribed a diet low in foods containing salicylates to a patient with hives whose psychiatric symptoms subsequently improved (Feingold 1985). While he initially called the regimen for management of hyperactivity the K-P Program standing for Kaiser Permanente, it became known in the press as the Feingold diet or program. He clinically observed that the dietary regimen of removal of foods he believed contained high levels of natural salicylates and contained synthetic food dyes and sweeteners resulted in subjective behavioral improvement in up to 30–50% of his patients. By 1979, he further recommended elimination of synthetic preservatives with subjective reports of improvement in 60–70% of his patients. While Dr. Feingold recommended limiting sweets, he at no time recommended elimination of sugar in the diet. His concern was about the additives in processed foods and recommended that families make treats and sweets from scratch that should be provided as part of a healthy diet.

He presented his observations regarding food and food additives and behavior to the American Medical Association in 1973. Much controversy ensued, with small clinical trials both reporting improvement in children on the restricted diet and other studies not being able to confirm these findings (Mattes and Gittelmann 1981). The National Institutes of Health convened a consensus development conference in 1983 to examine the data concerning defined diets and hyperactivity. The expert panel concluded that the data were insufficient to recommend defined diets for the treatment of hyperactivity but allowed that a diet trial could be considered by families after appropriate neurobehavioral evaluation and diagnosis took place with consideration of evidence-based

options (National Institutes of Health Consensus Development Panel 1983). Since that time, additional studies have been undertaken examining the behavioral effects of component parts of the Feingold diet. Wolraich et al. demonstrated that the artificial sweetener aspartame (Wolraich et al. 1994) does not impact attention. Studies on the effects of synthetic food coloring have been more controversial (reviewed in Schab and Trinh 2004). Synthetic food coloring use is restricted in European countries, but the scientific data have been interpreted to allow for continued use in the USA (Advisory Committee (March 30–31, 2011)).

Dr. Feingold's book – *Why is Your Child Hyperactive?* – was last published in 1985. The Feingold Foundation maintains an active society to support families who elect to pursue this dietary intervention (www.feingold.org).

Rationale or Underlying Theory

The original theory proposed for behavioral improvement with the Feingold diet was related to the elimination of allergens, leading to improved attention, learning, and behavior. Proponents point toward the introduction of increasing amounts of artificial flavors and colors in the diets of children as paralleling the increase in diagnosis of Attention Deficit Hyperactivity Disorder (ADHD). A hypothesis related to inhibition of neurotransmitter uptake of dopamine by FDC Red #3 was proposed but not confirmed in subsequent animal and human studies (National Institutes of Health Consensus Development Panel 1983). The lack of documentation of benefit in clinical trials and biologic mechanisms to explain clinical observations impacted the FDA decision to continue to allow synthetic food coloring (Advisory Committee (March 30–31, 2011)).

Goals and Objectives

The Feingold diet eliminates specific types of foods in the diet reported to be high in natural salicylates and processed foods containing

synthetic food colorings, sweeteners, and preservatives to promote behavioral improvement in attention, hyperactivity, irritability, and learning. Dr. Feingold managed over 600 of his patients with this approach and reported that up to two-thirds of the children improved. He reported that many children could be taken off of stimulant medications used to treat symptoms of ADHD once the diet was initiated. Dr. Feingold advised Connors et al. (1976) in the first clinical trial testing his hypotheses. Prospective studies attempted to examine the behavioral effects of the Feingold diet, artificial sweeteners, and/or food dyes and preservatives on the behavior of children in the learning laboratory, the classroom, and the home. Studies were designed to examine both behavioral change with implementation of the diet and the response to double-blind placebo-controlled challenges of specific agents. The studies are difficult to compare because of varied design features and the different goals and outcome measures of the individual studies. Some address only components of the diet (e.g., aspartame, specific food dyes). There is no consistency to the dosage of exposure of synthetic food coloring across studies.

Treatment Participants

None of the published studies specifically evaluates the utility of the Feingold diet for children with ASD. The studies evaluate children with ADHD, children with symptoms of hyperactivity, and/or community samples. There are several different sets of studies that examined components of the Feingold program that all approached identification of the study population in different ways. Many selectively recruited children whose families made the observation that their child improved behaviorally on the dietary intervention (Schab and Trinh 2004). Because of the difficulty in maintaining a restricted diet and cost of clinical trials, the double-blind placebo-controlled studies were all of relatively small size.

Studies that set out to evaluate the effect of the Feingold diet including all four components included the original trial by Connors et al.

(1976) that compared 15 children with ADHD to themselves in a 1-month crossover design. A crossover design was used to assess 36 children with hyperactivity without medication by Harley et al. (1978). While not the original Feingold diet, oligoantigenic diets where a few nonprocessed foods are initially permitted then other foods are sequentially added back have been studied more recently (Pelser et al. 2010) in children with behavioral symptoms.

Other studies examined the effects of sucrose or artificial sweeteners like aspartame on behavior. Wolraich et al. (1994) demonstrated no effect on cognition or attention from double-blind placebo-controlled challenges of aspartame in 25 typical preschool children and 23 school-aged children who were reported to have behavioral effects with sugar. In another report, Wolraich et al. (1995) summarized studies examining the effect of sugar on attention that included a total of 535 children. No significant effect was sustained across studies.

A third set of studies had as their goal the assessment of the behavioral effects of food dyes and preservatives on children. Mattes and Gittelman (1981) reviewed the literature and reported on 11 children with symptoms of ADHD who were recruited as responders to the Feingold diet. A meta-analysis of studies including 136 participants in randomized double-blind placebo-controlled studies that examined the effects of artificial food coloring was published by Schab and Trinh (2004). McCann et al. (2007) examined the behavioral response to two different concentrations of synthetic food dyes and sodium benzoate in two groups of children: 153 3-year-olds and 144 8- and 3-year-olds drawn from a diverse community sample and not selected for hyperactivity. Lok et al. (2013) compared the effect on attention in 130 8-year-old children in Hong Kong randomized to food coloring, sodium benzoate, or placebo delivered by capsule. There was no difference between groups studied.

A fourth type of study investigating the effect of increasing the nutritional value of foods provided a large population of public school students that included provision of foods with fewer synthetic ingredients (Schoenthaler et al. 1986).

Treatment Procedures

The study procedures are varied.

Diet introduction and maintenance: Most studies introduced the diet as part of the study or evaluated children already on the diet. Harley et al. (1978) provided all the foods to the families for the child under study to ensure that the diet was stringently followed. Some studies restricted other medications or supplements the children ingested. None formally analyzed and reported on the dietary sufficiency of the diet consumed or looked for other nutritional effects on behavior, although several commented on the overall sufficiency of the diet.

Dietary exposure to challenges: The studies that used a double-blind placebo-controlled approach to examine the behavioral effect of exposures typically provided a snack or beverage that contained synthetic food coloring, preservative, and/or aspartame at a standard time or times through the day. Some provided for repeat daily exposure for a week or more; others provided single challenges. At least one study examined the effect of time of day. Allowance for washout was not typically addressed and might impact the results of otherwise carefully done trials (Schab and Trinh 2004).

Measurement of change in behavior: Outcome measures will be discussed below. The study designs included subjective rating scales from parents, teachers, and research team members; laboratory tests of attention and learning; and objective measures of behavior largely in class settings.

Efficacy Information

The report of the NIH consensus development panel in 1982 was an accurate summary of the evidence available at that time and remains an appropriate summary of the efficacy information accrued over the subsequent 35 years:

- There are clinical reports of children whose parents observe that dietary restriction improved symptoms of hyperactivity.
- The scientific literature overall does not demonstrate a statistically significant improvement

in attention or hyperactivity as reported by laboratory tasks of inattention and impulsivity, clinician ratings, or teacher ratings with the defined diets that eliminate food dyes and food preservatives or alter the fruit and vegetable composition of the diet.

- There may be an impact on behavior in parent rating scales related to food dye exposure. It is unknown if this may be related to specific food dyes and preservatives, exposure, and/or age.
- Aspartame does not impact attention or hyperactivity.
- A defined diet should only be considered after diagnostic evaluation for ADHD and the implementation of educational and behavioral interventions. Families considering a trial of dietary intervention should have adequate information to weigh the potential benefit from conventional medications and should discuss their plan with their health-care provider. Data collection regarding change in target behaviors will help families determine if their behavioral goals are met by this intervention.

No controlled trials on the effects of the Feingold Diet have been completed in children with autism spectrum disorders. A recent review of dietary treatments by Millichap and Yee (2012) reiterates that dietary intervention may be preferred by some families but does not have the scientific support to endorse general use.

Outcome Measurement

The response to dietary interventions across studies is difficult to compare because different measures were used that capture different aspects of behavioral response.

Subjective response as reported by parents: Studies used a variety of parent report measures designed to capture the core symptoms of ADHD: impulsivity, inattention, and motor hyperactivity. The Conners scales have been validated and widely used by researchers studying hyperactivity (Schab and Trinh 2004). Other investigators compromised the interpretation of their studies

by developing their own measures that were not well validated (reviewed in Schab & Trinh).

Subjective response as reported by teachers: Teacher reports using the Conner's scales were common to many studies. This questionnaire is well validated and was widely used in the time period that many of these studies were completed. Schab and Trinh (2004) point out that teachers often rate children as more hyperactive than parents because of the tasks required during the school day.

Laboratory measures of attention and activity: Laboratory measures of vigilance and attention were used in several studies. Tests such as the Conner's Continuous Performance Test II were used by investigators to provide data on sustained attention and response inhibition on standard tasks that are impacted by inattention, impulsivity, and hyperactivity in children with ADHD.

Combination of outcome measures: While most investigators reported on individual measures by examiner, McCann et al. (2007) created a Global Hyperactivity Index to capture the results of the laboratory attention task, classroom observation and rating, and parent rating in a single score. The participants in their study were not selected for symptoms of hyperactivity and represented a community sample.

Measurement of behaviors other than ADHD: Few studies examined behaviors other than those related to attention and hyperactivity. Rowe and Rowe (1994) attempted to capture parent rating of irritability and sleep difficulties which were elevated in their report on exposure to food coloring. When parent report data are separated from the data collected by schools and clinicians, exposure to synthetic food coloring may be associated with increased behavioral symptoms (McCann et al. 2007; Schab and Trinh 2004). It may be that behavioral effects other than ADHD core symptoms are captured in the parent report data.

Qualifications of Treatment Providers

The advocates of this diet suggest that there is no harm in the removal of synthetic food colorings and preservatives and artificial sweeteners by the provision of a diet containing fewer processed foods.

The Feingold Foundation publishes a list of common products that meet their specifications, so implementation of the diet should be neither expensive nor onerous. Removal of a large number of the fruits and vegetables consumed in the American diet might have a nutritional impact if the necessary nutrients are not consumed in other forms. This has not been investigated. The diet recommends substitution of other foods such as bananas, cashews, and pears that the Feingold Foundation suggests are lower in natural salicylates. Reading food labels for processed foods for the presence of food dyes and preservatives may be challenging. Families who are considering a trial of dietary intervention should consult with their primary health-care provider. It may be helpful for families to be referred to a Registered Dietitian, a licensed professional with training that helps them understand the nutritional content of foods, for counseling regarding diet change and how to provide an adequate diet if supplemented, processed foods are eliminated. Not all fruits and vegetables are nutritionally equal, so children with food selectivity might require targeted supplementation.

A family considering a dietary intervention might also consult with their child's educational or behavioral providers to collect data on the behaviors they wish to change. This may be very helpful in determining if there is a behavioral effect that is clinically significant enough to continue intervention. Since the dietary intervention targets symptoms of ADHD, formal rating scales for ADHD in use in the school setting could be considered.

Definition

Fenfluramine is a drug with an incompletely understood mechanism of action. It was originally introduced for the treatment of obesity. It promotes the release of serotonin acutely but may have a serotonin-depleting effect over time. Given the replicated finding that at least a subgroup of children with autism are *hyperserotonergic*, investigators considered fenfluramine for the treatment of autism. Side effects were noteworthy. A randomized trial conducted in the mid-1980s showed that fenfluramine was no better than placebo. Since then, fenfluramine was removed from the market in 1997 when there were reports of pulmonary hypertension and damage to heart valves.

Feral Children

Lorna Wing
Centre for Social and Communication Disorders,
Bromley, Kent, UK

Definition

The term “feral” children is used to refer to children who are known, or are believed, to have been deprived of contact with other human beings or to have been neglected or treated inhumanely by a human being since infancy. They have had little or no experience of human love or care and no experience of human communication through spoken language. Some are thought to have been reared by animals. Accounts of such children can be found in myths, legends, fiction, and in stories believed to be true, though some have turned out to be hoaxes. The relevance for autism spectrum conditions lies in the inability to understand and speak and the odd behavior of many of the children and young adults, who are known or thought to have been deprived of human love and communication in their early years.

Historical Background

The accounts of such children in myths, legends, and fiction do not, however, have any link with

autism. The legend of Romulus and Remus is one example. They were twin brothers, sons of the god Mars. When very young, they were abandoned by the banks of the river Tiber, but were found by a she-wolf who fed them with her milk and sustained them until they were able to feed themselves. Later, they were found and given a home and care by a shepherd, and they grew up to be strong and clever. They decided to build a city on the place where the shepherd had found them – the legendary origin of the city of Rome. After it was built, they quarreled over who should be in charge, and Romulus killed Remus. Romulus became King of Rome, which he named after himself.

The most famous “feral” characters in fiction are Mowgli and Tarzan. Mowgli was a character in stories written by Rudyard Kipling. Mowgli’s parents were killed by a tiger in the Indian jungle when Mowgli was still a baby. He was found and reared by a mother and father wolf in a pack of wolves. He developed remarkable skills in hunting and tracking. He had close relationships with a black panther and a brown bear and was able to communicate with them. In the end, he returned to human society and had no problems communicating in human speech.

Tarzan was the fictional character invented by Edgar Rice Burroughs (although it has been suggested that he was influenced by the Mowgli stories). Tarzan’s parents died when he was a year old, and he was adopted by a group of great apes, the mangani, which is a species unknown to science! Tarzan’s jungle upbringing gave him remarkable abilities, beyond those acquired by most human beings. He was strong, agile, and well able to wrestle with all kinds of animals. He learned languages rapidly, including the language of the apes who reared him and other jungle animals and English, French, German, Latin, and ancient Greek, among others. He met and fell in love with a young American woman, Jane, whom he eventually married. They tried living together in England but found civilization hypocritical, so they returned to live in Africa.

The stories of Mowgli and Tarzan have been and are enormously popular and have led to many more books, as well as films, DVDs, television

programs, and even Disney cartoons. There seems to be something about these stories that people all over the world find endlessly fascinating. However, the fictional pictures of highly intelligent, gifted individuals who have learned languages and can communicate with animals and with human beings stand in stark contrast to the known facts concerning real “feral” children. Those in fiction bear no relationship to autism, unlike many of those, who, in real life, in their early years, were deprived of care and love from other human beings (Frith 2003a).

Current Knowledge

Another inappropriate use of the term “feral” children is to refer to those who live on the streets of cities. They are also known as “street” children. Such children have been deprived of family care because of neglect, or abuse, or parental death, or abandonment by poor parents who cannot afford to care for them. Large numbers of such children can be found in great cities throughout the world. Professor Martin Patt (2010) has created a website on which it is possible to find details of street children in different countries throughout the world. Patt emphasizes that such children can fall under the control of traffickers, who may disfigure the children in order to increase the money they can make by begging. The street children are also vulnerable to sexual abuse.

The suggestion of a link with autism is not appropriate especially for those street children who do not fall under the control of criminal adults. Typically, such children form their own gangs, with their own social rules and hierarchies to support each other and survive through various forms of criminal behavior. (See note on Romanian street children, Patt (2010) below.) They appear in fiction, for example, as the young pickpockets organized by Fagin in Charles Dickens’ book “*Oliver Twist*” or the street gangs, the “Baker Street Irregulars” who carried out various tasks for Sherlock Holmes in the stories by Sir Arthur Conan Doyle. They are quite different from the isolated child deprived of any human concern, care, and communication.

The children sometimes referred to as “feral,” whose history and behaviors are most relevant for any discussion of autism spectrum conditions, are those who have been deprived of human companionship and loving care for all or most of their infancy and childhood. There are accounts of children who are known or believed to have been kept in solitary confinement from very early in life, perhaps from infancy. These children have been given minimal basic feeding and minimal care by a human being who does not show them any love and companionship and does not communicate beyond simple orders. One of these unfortunate children was Kaspar Hauser, who appeared in Nuremberg in 1828, at the age of 16–17 years. A detailed account of Kaspar and his behavior was written by Anselm von Feuerbach (Feuerbach and Von Ritter 1833), then President of the Bavarian Court of Appeal at Anspael near Nuremberg. It seems that, during his first 16 years, Kaspar had been kept in a dark cellar. He had been fed on bread and water and had never seen his keeper. His only companion was a toy horse. When found in Nuremberg, he was able to say only a few phrases and fragments of speech. He preferred darkness to daylight and liked to sit on the ground with his legs stretched out in front of him. He had problems with distance vision, which could be linked to the fact that his vision had been limited by the darkness and walls of the cellar he had lived in.

His story is one of those discussed by Uta Frith (2003b). She notes that Kaspar rapidly learned to spell. He also showed social interest and affection towards children and adults who became close to him. He loved the toy horse he was given to replace the one he used to have in the cellar, and offered it a share of his food. He continued to have an odd gait, and he showed a marked preference for cleanliness and order for his possessions. Despite these continuing oddities, Professor Frith concluded that Kaspar was certainly not autistic – his social attachments and rapid improvement being strong indicators that he was not affected by this developmental disorder. Kaspar survived one attempt by a stranger to kill him. However, he was assassinated 5 years after his arrival in Nuremberg. The mysteries of his

origin, why he was kept in a cellar, why he was assassinated, and who killed him have never been solved, though there were unverified rumors that he was the unwanted child of a royal person.

A much more recent account of a child deprived of contact with loving human care and the outside world from early childhood is that of the girl known as Genie (not her real name). The psycholinguist who studied her, Susan Curtis (1977), referred to her as a modern-day “wild child.” Genie was born in the USA, the daughter of a violent, difficult father and a sad, frightened mother. She was the fourth and last child in the family, and was delivered by cesarean section. The first had died in infancy because his father objected to his crying and so kept him in the unheated garage where he developed pneumonia, which caused his death. The second child also died. The third, a boy, at 5 years, was taken into the care of his paternal grandmother, where his development, previously retarded, improved markedly, and he finally returned to his parents. At the age of 14 months, Genie developed pneumonia and was seen by a pediatrician, who suggested that she showed signs of retardation, though the pediatrician could not be sure because Genie had a high fever.

When Genie was 20 months old, her paternal grandmother died in a road accident. Genie’s father was intensely disturbed by this. He moved the family into his mother’s house and isolated them from the outside world. Genie was kept in a small bedroom, tied by a harness to a potty chair. At night, she was placed in a sleeping bag, which severely restricted her movements. Genie was kept secluded and had no toys to play with or radio to listen to. Her father hated any sort of noise, so conversation in the home was kept to a minimum and at a low volume. Genie’s father did not speak to her but barked and growled at her, and then beat her if she made any noises. She was fed baby foods that were stuffed into her mouth. This pattern of life for Genie lasted until she was 13½ years old, when her parents had a violent argument and Genie’s mother left her husband and home, taking Genie with her. After spending 3 weeks with the maternal grandmother, Genie was seen by a social worker, who sensed that

there were serious problems. Genie was admitted to hospital with severe malnutrition. The police were involved and charges brought against the parents. On the day of the trial, the father killed himself.

For 5 years from November 1970, when Genie was released from virtual captivity and isolation, her skills and disabilities were studied in detail by Curtiss and other colleagues. At first, she was very underweight and undersized and had major problems of self-care, movement, and distance vision. She was silent, even when sobbing, apart from a high-pitched whimpering and a few words. To quote from Susan Curtis (1977), “. . . she salivated copiously, spitting onto anything at hand. Genie was unsocialized, primitive, hardly human.”

Susan Curtiss analyzed in detail aspects of Genie’s ability with understanding and using language. Among other problems, Genie consistently confused *you* and *me*. She used entire phrases as labels, she failed to acknowledge questions, requests, etc., addressed to her. These are features also seen in children with autism spectrum disorders. Despite all this, Curtiss reports that Genie was alert and curious, avidly exploring her new surroundings. She was intensely eager for human contact and made good eye contact. These aspects of her behavior counteract any suggestion that she had an autism spectrum disorder. Susan Curtiss concluded that Genie appeared to be a “right hemisphere thinker.” She suggested that this was due to the deprivation of language experienced in her childhood.

Many questions relevant for a possible diagnosis of autism remain unanswerable. Was the pediatrician right in thinking that Genie was retarded when he or she saw her at 14 months, before her isolation? Did Genie show any of the odd hand and arm movements associated with autism, as well as her odd gait and posture? What was the underlying cause of Genie’s father’s bizarre behavior to his family – did he have a developmental disorder? There is no way of knowing.

Very relevant to the subject of children deprived of loving personal care and human communication from infancy or early childhood are the stories of the Romanian orphans. Nicolae Ceausescu was president of Romania from 1974

to 1989. During his presidency, birth control was made illegal in order to boost the population. The result was that many families had more children than they could possibly afford to care for, so these children were placed in state-run institutions. The care provided was minimal and often appallingly bad, and the children were kept in cots, deprived of human love, social interaction, and communication as well as lacking adequate nutrition and other health needs. In addition, during the Ceausescu regime, children who did not pass the state-organized physical and psychological assessments carried out on preschool children were also placed in institutions.

After the fall of Ceausescu and his regime, the sad life of the children in such institutions was publicized outside Romania. Some children from Romanian institutions were adopted by non-Romanian families, including some in the UK. A sample of 144 children who had experienced institutional care in Romania and who were later adopted by UK parents were assessed at ages 4, 6, and 11 years by Professor Michael Rutter et al. (2007; O'Connor et al. 2000; Rutter et al. 1999) They were compared with 52 non-deprived UK children adopted in the UK and placed before 6 months of age.

The children from Romania, when they arrived in England, showed marked signs of physical and psychological deprivation. They had been kept in their cots with no social or intellectual stimulation of any kind. The majority of the group showed remarkable catch-up by the time they were seen at 4 years of age. However, 16 children (11.1% of the sample of 144 children) showed "quasi-autism." Three of the 16 had IQs below 50, the rest having IQs above this level. These 13 children were studied in detail.

Their pattern of symptoms was called "quasi-autism" for specific reasons. While their scores on the ADI-R assessment at age 4 years were similar to a group of children with typical autism studied using the Autism Diagnostic Observation Schedule (Lord et al. 1994), their scores at age 6 years were significantly lower (less autistic) than those of the typically autistic children. There was also a tendency for the IQ scores to rise. They showed more flexibility in communication. Some showed

substantial social approaches, though of an abnormal kind, some being indiscriminately friendly. Those with "quasi-autism" had a much greater degree of cognitive impairment than the remainder of the adoptees from Romania. The sex ratio in the "quasi-autistic" children was approximately equal, compared with an excess of boys in the typically autistic children. Unlike the typically autistic children, the head circumference was not raised in those with "quasi-autism." The follow-up at 12 years showed that one quarter of the affected children had lost their autistic-like features by age 11 years.

Rutter and his team considered the possible causes of the "quasi-autistic" behavior, particularly in those (the majority) who did not have IQs below 50. They were significantly older than the rest when leaving institutional care to come to the UK. To quote from Rutter et al. (1999), "The quasi-autistic pattern seems to be associated with a prolonged experience of perceptual and experiential privation, with a lack of opportunity to develop attachment relationships and with cognitive impairment." The strongest predictor was the children's age of entry to the UK. Those adopted before 6 months showed almost complete physical and cognitive catch-up by 4 years. Those adopted between 6 and 24 months had lower scores on cognitive tests than those adopted before 6 months. Those adopted between 24 and 42 months had the lowest scores of all and a general developmental impairment. Rutter and his colleagues concluded that children adopted before 2 years of age were likely to show considerable resistance and to catch-up in cognitive and physical development.

The research team also found another 12 children who had some autistic-like features but not enough to qualify for "quasi-autism."

Future Directions

Dr. Sue Sheppard, a chartered specialist educational psychologist who is working in the field of developmental disorders and is a consultant to the NAS Diagnostic Centre, went to Romania in 1992 as one of the group of professionals whose

aim was to help the children in the state institutions. Among the children in the institutions, Sue Sheppard (personal communication, in conversation with the author in December 2010) found a small minority who quite clearly had autism spectrum disorders. This is not surprising, since parents who sent or abandoned children to institutions would be likely to select those whose behavior was challenging or whose development was clearly abnormal. Furthermore, state-implemented preschool screening tests would identify those with developmental disorders. In addition to those who were clearly in the autism spectrum, there was another minority who had some autistic traits, especially odd movements and other repetitive behaviors, and who were not socially responsive, though they did not present the full picture of an autism disorder. They closely resembled the children Rutter and colleagues described and called “quasi-autistic” (see above). Unlike those with clearly diagnosable autism, these children showed definite improvement over a period of time when given loving care and help by people who understood their problems, who came from relief agencies from other countries, sent in response to the problems children were having in Romania. These children’s physical health and intelligence levels also improved markedly. The majority of the institutionalized children did not show either of the above abnormal behavior patterns, seeming to be highly resistant despite the deprivation suffered. This was most likely to be the case if, as Rutter and his team also found, the children were under 2 years old when their living conditions were improved.

Sue Sheppard also observed another group of children, often described as “wild” or as “bandits.” These were children who lived in gangs on the streets and were sociable according to the values of the group they were with. They had become “street children” for various reasons, including having run away from abusive parents or institutions. They could smile sweetly and act in a charming way in order to get near enough to someone to steal from them. Although their behavior was antisocial from the point of view of society as a whole, as a group, they had their

own social system, which certainly does not fit with a diagnosis of autism spectrum disorder.

The last group of “feral” children to be discussed here are those who are given the name “feral” because they are thought to have been reared by animals in their early childhood years. Stories of such individuals found wandering, captured, and reintroduced into human society can be traced back to the 1300s. Lucien Malson (1972) gives a list of 53 “feral” children recorded from 1344 up to 1961. Wikipedia adds another 10 in the years from 1961 to 1999 and 8 from 2000 to 2009. The animals alleged to have cared for the children include wolves, cows, pigs, sheep, leopards, bears, chimpanzees, monkeys, dogs, goats, and gazelles. A few children were actually found with animals (most such accounts are of children found with packs of dogs), but there is no direct evidence of them being suckled by the animals in their infancy. Several of the stories are known or thought to be fictitious, including the two that described children reared by gazelles. Where sufficient contemporary information is available, it is clear that those thought to have been reared by animals lacked basic social skills. The great majority of those reported did not learn to speak or else managed only a few words; they had problems learning to walk upright and to use a toilet and had no interest in other human beings or human activity.

The one “feral” child concerning whom we have a considerable amount of information is the “wild boy of Aveyron.” This boy was found in 1798 wandering naked and wild in the woods in south-central France. He was captured and eventually given into the care of the physician Dr. Jean Marc Gaspard Itard and his house keeper, Madam Guerin. Itard wrote two detailed reports in 1801 and 1806 (see English translations, Itard 1962) describing the boy’s behavior and his progress in learning the skills that Itard tried to teach him.

When captured, Victor (the name given him by Itard) was thought to be about 12 years old, though small for his age. He had many scars on his body and limbs including one across his throat. He had been glimpsed in the forest on occasions for 2 years before his capture, so it seemed that he had lived in the wild at least from around age 10 up to 12 years.

In her book on autism, Uta Frith (2003c) includes a detailed discussion of the evidence concerning the possibility that Victor had autism. The relevant aspects of his behavior, as described by Itard, are as follows.

Victor showed no marked social attachment to anyone. He showed some attachment to his caretakers, Dr. Itard and Madame Guerin, which seemed to be due to the fact that they provided his food. He showed no sympathy and no evidence that he had any concept of other people's ideas, wishes, or feelings. He had no ability to conform to any social rules.

Victor made various noises but did not learn to speak. He did learn that the word "lait" referred to milk, but never used it to request milk, only as a label when he was given milk. He used limited nonverbal ways of communicating the few messages he wished to communicate. For instance, he enjoyed having Dr. Itard touch and stroke his head and would take Itard's hand and place it on his head to indicate what he wanted. He never showed any evidence of pretend play or imaginative skills.

As is typical in autism, Victor did respond in unusual ways to various kinds of sensory input (Leekam et al. 2007). He ignored most sounds, however sudden and loud, but turned at once to the sound of a nut cracking (nuts being a favorite food), however faint the sound. He seemed oblivious of heat, cold, or pain. This was one of the possible reasons why he could exist for at least 2 years in the wild.

He would wake early in the morning, wrap his head and body in his blanket and rock himself back and forth. He would lie down from time to time and then rock again until it was time for breakfast. He was fascinated by the moonlight, and would sit and watch the moon while rocking himself.

Despite lack of language skills, Victor was very efficient at shelling and preparing beans for cooking, including picking out any that were bad. He learned to carry out some other practical domestic tasks that did not require language to perform.

These behaviors indicate impairment of social interaction, communication, and imagination, and a preference for repetitive routines (rocking),

which are diagnostic of an autism spectrum disorder. Uta Frith considers that it is highly likely that Victor had such a disorder. The present writer agrees with her, though, from such a distance in time, there can be no absolute certainty.

Harlan Lane (1979), professor of social psychology, does not accept that Victor could have had an autism spectrum disorder. However, the aspects of Victor's behavior he lists as evidence that would exclude a diagnosis of autism could be seen in many children with this diagnosis. Lane notes that Victor was not totally aloof and indifferent to others. For example, as already mentioned above, Victor did show some signs of attachment to Dr. Itard and to Madame Guerin, who were his careers. There is an account of him weeping when reproached by Itard. But many children with typical autism spectrum disorders are not totally aloof – their social behavior is limited and can be inappropriate. Lane appears to be aware only of the most severe manifestations of autism and not the wide range of behavior across the whole autism spectrum and the changes that can occur with increasing age and the positive effects of education and of loving care.

While it is highly likely that Victor was in the autism spectrum and a few other "feral" children were clearly not autistic, for the great majority of cases of "feral" children, a diagnosis of autism or at least autistic traits appears to be a possibility, but there is rarely enough evidence to be certain.

A question that inevitably arises in any discussion of "feral" children is whether the autism spectrum disorder is due to biological causes and was present from birth (Feinstein 2010; Frith 2003d), leading to the child's loss or abandonment, or whether the lack of loving human care was the cause (Bethelheim 1967). The available information on "feral" children cannot provide an answer to this question. The known cases of "feral" children are just a minute fraction of all those with autism spectrum disorders. The latest prevalence studies suggest that around 1% or more of children and adults have some form of this disorder (Gillberg and Wing 1999; Wing 2004; Wing and Potter 2002). Research into the nature and origins of autism has shown that autism spectrum disorders are most likely to be due to

genetic or other biological causes (Feinstein 2010; Frith 2003d). The amount of progress possible for those with autism has been shown to be linked to their innate level of ability, as measured by IQ tests, though the prognosis even for those with IQ over 70 is very variable (Beadle-Brown et al. 2006; Howlin et al. 2004).

Another question that has not been answered concerns whether there is a “critical” or “sensitive” period for the acquisition of language. The critical period hypothesis holds that there is a limited time in early childhood when language can be acquired in response to exposure to facilitative speech presented by caretakers. If a child is deprived of this essential experience during the appropriate age period, he or she will not learn to understand and speak (Lenneberg 1967). It has been suggested that the histories of “feral” children support this theory. The findings of Rutter et al. concerning the importance of removal to a supportive environment before 2 years, described above, do provide some support. The problem is that there is no way of knowing whether or not the “feral” children who do not speak suffered from autism, or a developmental language disorder, or intellectual disability, as the reason why they did not speak and did not learn language when education was provided.

The sad truth is that the stories of “feral” children in all their variation, in most cases, present fascinating but insoluble mysteries. The questions they raise can only be solved (if at all) by appropriate modern research.

Ferster, C.B.

A. Charles Catania
 Department of Psychology, UMBC (University of Maryland, Baltimore County), Baltimore, MD, USA

Name and Degrees

Charles Ferster

Ferster, Charles Bohris (Nov. 1, 1922–Feb. 3, 1981).

B.S. (Rutgers University, 1947), M.A. (Columbia University, 1948), Ph.D. (Columbia University, 1950).

Major Appointments (Institution, Location, Dates)

- US Army Air Force, 1943–1946
- Research Fellow under B. F. Skinner, Harvard University, 1950–1955
- Postdoctoral Research, Yerkes Laboratory, Emory University, 1955–1957
- Postdoctoral Research, Indiana University Medical Center, 1957–1962
- Institute for Behavioral Research (Silver Spring, MD), 1962–1968, as Executive Director (1962–1963), Associate Director (1963–1965), Senior Research Associate (1965–1968)
- Professor of Psychology, Georgetown University (Washington, DC), 1967–1968
- Professor of Psychology, American University (Washington, DC), 1969–1981 (Department Chair, 1970–1973)

Major Honors and Awards

- First Editor and Executive Editor of the *Journal of the Experimental Analysis of Behavior*, 1958–1961.

Landmark Clinical, Scientific, and Professional Contributions

With B. F. Skinner, developed the experimental methods of the experimental analysis of behavior, including the design of apparatus and procedures, especially with regard to schedules of reinforcement.

Participated in the founding of the first major journal in the field, the *Journal of the Experimental Analysis of Behavior*.

Extended the basic principles of behavior analysis to clinical problems and to education, in areas

such as clinical depression, psychotherapy, and individual instruction.

Distinguished between the natural consequences of behavior and the arbitrary consequences that must be arranged when for some reason the natural consequences are not effective.

Opened the way to the treatment of autism by demonstrating that the behavior of the autistic child is sensitive to its consequences.

Short Biography

Charles B. Ferster was a pioneer in the experimental analysis of behavior and its extension to areas of application. His undergraduate career at Rutgers University was interrupted by service in the US Army Air Force during World War II. Upon completing his Rutgers B.S. in 1947, he entered the graduate program in Psychology at Columbia University. There Fred S. Keller, with W. N. Schoenfeld, had established a curriculum based on B. F. Skinner's analysis of behavior (Keller and Schoenfeld 1949, 1950). Keller referred Ferster to Skinner at Harvard University, and Ferster, completing his Ph.D. in 1950, moved to Harvard as Skinner's research assistant. Once there, he developed many innovations in methodology and in the automation of Skinner's pigeon laboratory, summarized in a journal article that became a guide for many other researchers (Ferster 1953). By 1957, he and Skinner had published a seminal book, *"Schedules of Reinforcement"* (Ferster and Skinner 1957), that detailed the properties and the results of these novel procedures in the analysis of behavior. Skinner was sufficiently impressed by Ferster's contributions to the research enterprise that he gave Ferster first authorship.

Behavior is maintained by its consequences, as when a pigeon's key peck or a rat's lever press occurs frequently because it produces access to food. This property of behavior is called reinforcement; reinforcement is not a theory but rather is simply a name for a ubiquitous phenomenon. What Skinner discovered about reinforcement in his earlier research (Skinner 1938), and what he and Ferster explored in depth, was that the maintenance of behavior by reinforcement depends

crucially on the contingencies arranged for responses, their schedules of reinforcement. In the real world as well as in the laboratory, not every response is reinforced. In what is called a ratio schedule, for example, only some fraction of responses is reinforced, as when some percentage of bets pays off; one must play to win, but one will not win every time. In what is called an interval schedule, however, whether a response is reinforced depends on when the response occurs rather than on how many responses have occurred, as when one finds mail in one's mailbox only if checking it after the mail has been delivered; checking more often will not affect when the mail comes. A full account of reinforcement schedules, which include both fixed and variable versions of ratio and interval schedules as well as other categories of contingencies, is beyond the scope of this article. For the present purposes, the crucial point is that different schedules produce and maintain very different patterns of behavior. For example, ratio schedules typically maintain substantially higher rates of behavior than do interval schedules, and details of the schedules determine the patterning of behavior over time (e.g., some schedules produce relatively constant responding, others produce gradual increases, and still others produce abrupt shifts from not responding to high rates of responding). Schedules of reinforcement soon became commonplace procedures for the study of a broad range of topics, such as the analysis of sensory processes, effects of psychopharmacological agents, and motivational operations.

One procedure studied by Ferster (1954) involved using a blackout, turning off the lights in the pigeon chamber and therefore eliminating the pigeon's opportunity to produce food. The name was later changed to time-out, and it was discovered that time-outs were sometimes useful because they could be used to reduce behavior, as when errors in some visual task produced time-outs from positive reinforcement. The use of time-out in some behavioral programs and eventually by some parents and teachers evolved from this early pigeon research.

In those early days of operant research, extending the basic results from the animal

laboratory to significant human problems had just begun. Examples were Fuller's (1949) demonstration that reinforcers could be effective even on the behavior of a vegetative human, work by Lindsley (1956) showing the effects of schedules of reinforcement on the behavior of adult psychotic patients, and Bijou's (1957) extensions to the study of child development. After moving to a postdoctoral position at the Medical Center at Indiana University in 1957, Ferster undertook an extension of his work with schedules of reinforcement to the behavior of autistic children. In those days, diagnostic criteria were highly variable, and such children were often described in terms of early-stage schizophrenia. More important, the classification of autism implied individuals who were virtually confined within themselves, impervious to events in their environments. Ferster, in collaboration with DeMyers (Ferster and DeMyer 1961, 1962), arranged laboratory settings functionally similar to those used in the analyses of reinforcement schedules and found that when appropriately arranged food and candy and trinkets could become effective reinforcers of the behavior of these children. Other studies examined ways in which these reinforcers might eventually provide a foundation for building social reinforcers, which are typically ineffective with these children (DeMyer and Ferster 1962). The research also showed that food could be used to make coins effective as conditioned reinforcers and that reinforcers could be arranged so as to enhance the attention of these children to some of the stimuli around them.

Beyond the fundamental observation that the behavior of these children could be reached through reinforcement schedules, albeit more slowly than with children without these deficits, this research provided the precedent for extensions that were soon to follow, including work by Lovaas and others (e.g., Lovaas et al. 1965, 1966). In his basic research, Ferster had shown that relatively simple and small changes in the contingencies arranged by reinforcement schedules could produce profound changes in ongoing behavior, and he brought these observations to bear in his subsequent work, which moved to analyses of other clinical deficits and pathologies,

such as clinical depression (Ferster 1965, 1972, 1973). Some additional contributions Ferster has made to the analysis of behavior have been described by Keller (1981) and by Skinner (1981).

Fetal Alcohol Spectrum Disorder

John Thorne
Department of Speech and Hearing Sciences,
University of Washington Fetal Alcohol
Syndrome Diagnostic and Prevention Network,
Seattle, WA, USA

Synonyms

[Alcohol-related neurodevelopmental disorder](#);
[Fetal alcohol effects](#); [Fetal alcohol syndrome](#)

Short Description or Definition

Used to refer to the range of negative outcomes associated with prenatal ethyl-alcohol exposure,

fetal alcohol spectrum disorders (FASD) is an umbrella term that describes a heterogeneous set of permanent birth defects. When an FASD includes growth deficiency, a unique cluster of three minor facial anomalies (i.e., small eyes, a thin upper lip, and a smooth philtrum), and evidence of central nervous system (CNS) abnormalities, it is referred to as *fetal alcohol syndrome* (FAS). Other FASD can include any combination of these impairments in the context of confirmed prenatal alcohol exposure. CNS abnormalities are the most common impairment found in individuals with an FASD. FASD may also include ophthalmologic, otologic, cardiac, renal, and orthopedic abnormalities.

Categorization

Diagnostic categories
FAS, alcohol exposed
FAS, alcohol exposure unconfirmed
Partial FAS, alcohol exposed
Sentinel physical finding(s) with static encephalopathy, alcohol exposed
Static encephalopathy, alcohol exposed
Sentinel physical finding(s) with neurobehavioral disorder, alcohol exposed
Neurobehavioral disorder, alcohol exposed
Sentinel physical finding(s), alcohol exposed

Epidemiology

Although the impact of maternal drinking on the pre- and postnatal development of children was examined as early as the late nineteenth century (Sullivan 1899), teratogenic effects of prenatal ethyl-alcohol exposure were not characterized until the late 1960s (Lamache 1967) and not widely recognized until the work by Smith and colleagues in 1973 (Jones et al. 1973). The *fetal alcohol syndrome* (FAS) they described is now recognized internationally as a permanent birth defect syndrome resulting from prenatal alcohol exposure and is understood to include growth deficiency, a unique cluster of three minor facial anomalies (i.e., small eyes, a thin upper lip, and a

smooth philtrum), and evidence of central nervous system (CNS) abnormalities. Subsequent work has shown that significant impairments are frequently found in children with prenatal alcohol exposure even in the absence of the full set of symptoms required for a diagnosis of FAS. Over time, the term fetal alcohol spectrum disorders (FASD) has come to be used to describe the full range of impairments associated with prenatal alcohol exposure. FAS is the most easily recognized FASD, largely because the distinctive FAS facial phenotype provides a specific diagnostic marker of prenatal alcohol exposure (Astley 2004a). With prevalence of FAS estimated at 1–5 cases per 1,000 live births, it is the leading known preventable cause of developmental and intellectual disabilities. Given lifetime costs for FAS estimated at two million dollars per case (Lupton et al. 2004), FAS is estimated to have an annual cost in the United States in excess of five billion dollars (Riley and McGee 2005). FASD that lack the telltale facial features of FAS are more difficult to diagnose, but share a similar range and severity of central nervous system impairments and social costs. With numbers approaching 1% of all children, other FASD are many times more prevalent than FAS (Bailey and Sokol 2008).

Natural History, Prognostic Factors, and Outcomes

The impairments associated with prenatal ethyl-alcohol exposure are permanent birth defects that effect on the developing system throughout the life course of individuals with fetal alcohol spectrum disorders (FASD). The degree and extent of damage caused by prenatal alcohol exposure is both dose and timing dependent, and the central nervous system is the most vulnerable body system. Individuals with FASD are at risk for learning, behavioral, and mental health impairments throughout their lives. Protective factors that reduced the chances of negative outcomes in individuals with prenatal alcohol exposure and/or FASD include early diagnosis, stable home placement with quality care, protection from violence,

absence of substance abuse in the home, and the presence of appropriate social services. Early intervention in a coordinated system of care that maximizes these protective factors may reduce the chances that children with FASD will experience negative outcomes and should support their chances of success as they grow to adulthood (Streissguth et al. 2004).

Clinical Expression and Pathophysiology

The degree and extent of damage caused by prenatal ethyl-alcohol exposure is both dose and timing dependent. The central nervous system (CNS) is the most vulnerable body system, and various regions, developmental processes, and cell types in the CNS are differentially vulnerable to prenatal alcohol exposure at different stages of development. Prenatal alcohol exposure changes many ontogenetic processes in the developing CNS—disrupting or distorting neurulation and neural tube development, neuronal proliferation and migration, synaptogenesis, neuronal differentiation, and apoptosis. Prenatal alcohol exposure alters the hormone balance in the system as well as astroglial development and gene expression. Alcohol interferes with gliogenesis and development, delays myelination, and causes changes in the production of important neurotrophic factors (e.g., cell adhesion molecules such as the integrins and laminins) and neurotransmitters such as glutamate, NDMA, and serotonin.

Neurological Abnormalities

As expected, given its impact on developmental processes, prenatal alcohol exposure is associated with structural abnormalities throughout the CNS. These can include microcephaly, microgyria, gray and white matter defects, heterotopias, and regional hypoplasia. Imaging studies of the population with FASD are in their early stages, but some trends are emerging in the findings. Studies using functional magnetic resonance imaging and electroencephalography consistently find atypical results suggesting abnormal processing and development in individuals with prenatal alcohol exposure (e.g., D'Angiulli et al. 2006). The few

magnetic resonance spectroscopy studies conducted have all found differences in neurochemical profiles associated with prenatal alcohol exposure (e.g., reduced choline; Astley et al. 2009). Prenatal alcohol exposure can result in reduced frontal lobe volume relative to overall brain volume particularly in the presence of FAS facial features (Astley et al. 2009). There is also emerging evidence that temporal and parietal lobes may also be disproportionately vulnerable to prenatal alcohol exposure with exposure resulting in reduced volume of these structures. The caudate nucleus of the basal ganglia seems particularly sensitive to prenatal alcohol exposure (Astley et al.), while the putamen, amygdala, and hippocampus seem relatively resistant to damage from prenatal alcohol exposure (Spadoni et al. 2007).

Findings related to the volume of the cerebellar vermis (CV) are equivocal (e.g., Astley et al. 2009), making it unclear whether findings of reduced CV in children with FASD result from smaller overall brain size or not. However, when found in children with FASD, reduced volume of the CV is associated with deficits in verbal learning tasks. The effects of prenatal alcohol exposure on the corpus callosum (CC) are also not clear, but there is a consistent finding across studies of shorter CC, with some regions of the CC apparently more sensitive to prenatal alcohol exposure than others (Astley et al.). When they are found, CC abnormalities are associated with functional deficits.

Neuropsychological Findings

Neuropsychological impairments have been documented across a variety of domains in children with FASD. Deficits may include impairments of attention, motor and choice reaction time, visual spatial learning, fine/gross motor control and balance, response conditioning, executive function, working memory, mathematical reasoning, nonverbal inductive reasoning, and information processing (Kodituwakku 2007). Communication deficits are among the most frequently reported in FASD literature, and peripheral and central hearing impairments are common in FAS. Differences in IQ between children with

prenatal alcohol exposure and their unexposed peers are well documented. However, in the FASD population, IQ scores cover the range from profoundly handicapped to above average intelligence. Although lower IQ scores have been shown to be associated with the presence of the face of FAS and increased prenatal alcohol exposure levels, even among children with FAS, approximately 75% have IQ scores above 70 (Riley and McGee 2005).

Executive Functioning, Attention, and Behavioral Regulation: The caudate nucleus of the basal ganglia and the frontal lobes, structures which support executive functioning, seem particularly vulnerable to PAE, and impairments of executive function appear widespread in FASD. The most commonly reported concern is inattention. Deficits in planning, set shifting, problem solving, verbal and nonverbal fluency, and working memory are also commonly described. Deficits in social skills and adaptive functioning are widely reported, as are clinically significant problems maintaining appropriate behaviors (Kodituwakku 2007; Riley and McGee 2005).

Communication: Communication deficits have been documented for children with FASD in all areas of language and communication. These include impairments in auditory processing, phonology, morphosyntax, semantics, and integrative language/pragmatics. Later-developing discourse-level communication skills such as narrative storytelling may be particularly vulnerable to prenatal alcohol exposure (e.g., Coggins et al. 2007).

Sensory-Motor Development: Children with FASD frequently have deficits in fine motor, gross motor, and visual-motor abilities (Riley and McGee 2005). These can include delayed achievement of early motor milestones, tone abnormalities, tremulousness, and oral-motor (e.g., suck-swallow) difficulties. Older children with FASD may experience impaired balance, reduced fine motor control, visual spatial problems, and motor immaturities. The poor sensory modulation commonly described among clinic-referred children with FASD may play a role in motor and postural deficits and poor behavioral regulation (Jirikowic et al. 2008).

Mental Health: Mental health and psychiatric problems are found at high rates among clinical samples of individuals with prenatal alcohol exposure. Indeed, even low levels of prenatal alcohol exposure have been shown to increase risk of clinically significant mental health issues in young girls. Other adverse pre-/postnatal risk factors commonly associated with prenatal alcohol exposure (e.g., polydrug exposure, abuse/neglect) may exacerbate early biologic vulnerability and increase the risk for secondary disabilities later in life (Streissguth et al. 2004).

Evaluation and Differential Diagnosis

Fetal alcohol spectrum disorder (FASD) diagnoses are based on the degree of presentation of (1) prenatal and/or postnatal growth deficiency, (2) the fetal alcohol syndrome (FAS) facial phenotype, and (3) central nervous system (CNS) abnormality, in the context of (4) prenatal alcohol exposure. There are several competing diagnostic systems used in the diagnosis of FASD. This discussion of FASD diagnosis will be structured around the most established system, the FASD *4-Digit Diagnostic Code* (3rd edition, Astley 2004a: diagnostic guidelines, Lip-Philtrum Guides, and facial measurement software available at www.fasdpn.org). The other major diagnostic systems, the *Canadian Guidelines for FASD Diagnosis* (Chudley et al. 2005) and the *Guidelines for Identifying FAS* from the Centers for Disease Control (CDC; Bertrand et al. 2005), incorporate methods/tools from the *4-Digit Diagnostic Code* but use different diagnostic criteria.

In individuals being assessed for an FASD, as the presentation of key features of FAS move from not characteristic to highly characteristic of FAS, the *4-Digit Diagnostic Code* quantifies the expression of these features using a set of four 4-point Likert ranks that move from 1 to 4. The 4-digit code is created by combining these four Likert ranks from left to right in the order GROWTH, FACE, CNS, and PRENATAL ALCOHOL EXPOSURE (PAE). This numeric code is then used to assign an individual the appropriate

FASD diagnosis. A brief summary of how each Likert rank is determined is presented below.

Growth

In the *4-Digit Diagnostic Code*, a GROWTH rank of 1 is given when both prenatal and postnatal height and weight are above the 10th percentile; a GROWTH rank of 2 indicates that either prenatal or postnatal height, weight, or both are above the 3rd percentile, but less than or equal to the 10th percentile; a GROWTH rank of 3 indicates that either prenatal or postnatal height or weight is less than or equal to the 3rd percentile; and a GROWTH rank of 4, severe growth deficiency, is given when both height and weight are less than or equal to the 3rd percentile during either the prenatal or postnatal period.

The FAS Facial Phenotype

Three key facial features are considered diagnostic of FAS: (1) small eyes with palpebral fissure length (PFL) more than 2 standard deviations (SD) below the mean for age; (2) smooth philtrum consistent with a rank 4 or 5 on the University of Washington Lip-Philtrum Guide; and (3) thin upper lip consistent with a rank 4 or 5 on the University of Washington Lip-Philtrum Guide. *At these values*, this constellation of features has high specificity for prenatal ethyl-alcohol exposure, and their presence can serve as a proxy indicator of prenatal alcohol exposure when exposure is unknown (Astley 2006). In the *4-Digit Diagnostic Code*, a FACE rank of 4 indicates that all three facial features are present; a FACE rank of 3 indicates that deficits have been measured in all three features, but that one is only moderately impacted (e.g., PFL between -1 and -2 SD or a lip/philtrum Likert of 3); a FACE rank of 2 indicates that at least one feature is present; and a FACE rank of 1 indicates that there are no features present. Increased FACE rank is associated with increased risk/severity of CNS abnormality (Astley et al. 2009).

Central Nervous System (CNS) Integrity

The *4-Digit Diagnostic Code* includes a nested ranking of CNS abnormalities. This ranking quantifies both evidence of structural abnormality and

severity of functional impairment. A CNS rank of 4 indicates that there is direct structural/neurological evidence (e.g., microcephaly, seizures) of a “definite” abnormality in CNS structure; a CNS rank of 3 indicates that there is a “significant” functional impairment in three or more domains of brain function (i.e., a deficit >2 SD on a standardized test); a CNS rank of 2 indicates mild to severe impairment in some domain of functioning; and a CNS rank of 1 indicates that the individual does not meet criteria for CNS ranks of 2 through 4.

Documenting Prenatal Ethyl-Alcohol Exposure (PAE)

The *4-Digit Diagnostic Code* includes 4 exposure ranks. A PAE rank of 4 indicates a “confirmed exposure to high levels of alcohol.” Blood alcohol concentration greater than 100 mg/dL present on a weekly basis is given as a general guideline for defining “high levels” of exposure (Astley 2004a, p. 43). A PAE rank of 3 indicates “confirmed exposure” of either unknown quantity or of an amount that falls short of a PAE rank of 4. A PAE rank of 2, “unknown exposure,” indicates that exposure cannot be confirmed present nor absent. A PAE rank of 1 indicates a “confirmed absence of exposure from conception to birth.”

Diagnostic Categories

When combined, ranks for GROWTH, FACE, CNS, and PAE provide a *4-Digit Diagnostic Code*. This code can then be converted into 1 of 22 possible diagnoses. Eight of these fall under the umbrella of FASD. Importantly, only a diagnosis of FAS implies a causal role for prenatal alcohol exposure in producing the impairments identified during assessment. This causal inference is grounded in the specificity of the FAS facial phenotype to prenatal ethyl-alcohol exposure. For this reason, both FAS diagnoses in the *4-Digit Diagnostic Code* require a FACE rank of 4 (FAS = GROWTH 2–4, FACE 4, CNS 3–4, PAE 2–4). The other 6 FASD diagnostic categories simply describe the degree and type of impairment and document prenatal alcohol exposure. The eight FASD categories from the *4-Digit Diagnostic Code* are:

Diagnostic category	4-Digit code criteria
FAS, alcohol exposed	GROWTH 2–4, FACE 4, CNS 3–4, PAE 3–4
FAS, alcohol exposure unconfirmed	GROWTH 2–4, FACE 4, CNS 3–4, PAE 2
Partial FAS, alcohol exposed	GROWTH 1–4, FACE 3, CNS 3–4, PAE 3–4
Sentinel physical finding(s) with static encephalopathy, alcohol exposed	GROWTH 3–4, FACE 1–2, CNS 3–4, PAE 3–4
Static encephalopathy, alcohol exposed	GROWTH 1–2, FACE 1–2, CNS 3–4, PAE 3–4
Sentinel physical finding(s) with neurobehavioral disorder, alcohol exposed	GROWTH and/or FACE 3–4, CNS 2, PAE 3–4
Neurobehavioral disorder, alcohol exposed	GROWTH 1–2, FACE 1–2, CNS 2, PAE 3–4
Sentinel physical finding(s), alcohol exposed	GROWTH and/or FACE 3–4, CNS 1, PAE 3–4

In the *Canadian Guidelines for FASD Diagnosis*, there are four FASD diagnoses. These diagnoses are based on the *4-Digit Diagnostic Code* and include two FAS categories: FAS, alcohol exposed; and FAS, alcohol exposure unconfirmed. The *Canadian Guidelines* use loosened facial criteria for FAS compared to the *4-Digit Diagnostic Code*. In the Canadian system, FAS can be diagnosed with the following ranks: GROWTH 2–4, FACE 3–4, CNS 3–4, and PAE 2–4. The *Canadian Guidelines* diagnosis of Partial FAS is also a broader category than in the *4-Digit Diagnostic Code* and includes a FACE rank of 2. The final diagnostic category in the Canadian system is alcohol-related neurodevelopmental disorder (i.e., ARND), which corresponds to the *4-Digit Diagnostic Code* diagnoses of static encephalopathy with or without sentinel physical findings.

The Centers for Disease Control’s *Guidelines for Identifying FAS* has the most liberal FAS diagnostic criteria. CDC guidelines relax requirements for eye size to include PFL as large as 10th percentile. The CDC guidelines also relax criteria for CNS impairment and only require mild functional impairments (i.e., one standard deviation from the mean below the 16th percentile) in three domains of functioning for a diagnosis of FAS.

Treatment

Evidence-based interventions for fetal alcohol spectrum disorders (FASD) are emerging in the literature (Premji et al. 2007). Currently, primary prevention and direct individualized instruction to remediate specific learning and/or behavior problems are the primary tools available for treating individuals with FASD. Because children with FASD commonly face disruptive challenges from their environment as well as complex neurophysiologic deficits (Coggins et al. 2007), successful treatment for this population demands multimodal services. These services should incorporate the knowledge and expertise of multiple disciplines (e.g., medicine, psychology, social work, special education, speech-language pathology, audiology, occupational therapy) in order to remediate both environmental barriers to success and central nervous system (CNS) dysfunction.

Primary Prevention: FASD are entirely preventable, and simple, low-cost informative counseling directed at women who use alcohol and are pregnant or thinking about pregnancy can decrease FASD risk (Bailey and Sokol 2008). More intensive interventions for women at high risk who have already given birth to one child with prenatal alcohol exposure are also important. For example, the *Parent–Child Assistance Program* (Grant et al. 2005) provides participants with a paraprofessional advocate throughout their pregnancy and for 3 years after their child is born. The program helps mothers to decrease or eliminate their use of alcohol and/or to use family planning to prevent pregnancies when using alcohol. The program also promotes addiction recovery, supports economic and personal self-sufficiency, and helps participants connect to community resources.

Screening: Screening in high-risk populations has also been demonstrated to be effective in reducing FASD (e.g., Astley 2004b). The state of Washington, for example, developed an effective program for screening children in the foster care system by using a review of medical records and facial photograph. In the program, those children with a positive screen for the FAS facial phenotype or for CNS damage (e.g., microcephaly) are

invited for a diagnostic evaluation. Benefits from this kind of program include early diagnosis, earlier access to community supports and services, and increased caregiver knowledge regarding signs and symptoms of FASD.

Medical Interventions: Medical providers play an important role in FASD prevention, screening, diagnosis, and treatment. Early referrals to appropriate service providers are of particular importance and should always include formal vision and audiological screenings. Because efficacy and safety data on psychotropic medications are not generally available for the FASD population (Premji et al. 2007), there is little guidance for providers on how to target specific psychiatric or behavioral symptoms associated with FASD. Children with FASD may be at risk for paradoxical reactions and can be more sensitive to dosing. While research using animal models has revealed a number of promising medical approaches for protecting against or even reversing the long-term impacts of alcohol exposure, a more rigorous evidence base needs to be established before these approaches can play a major role in FASD treatment. Avenues being pursued include perinatal choline supplementation, prenatal folic acid, exercise training, and postnatal aniracetam treatment.

Educational and Behavioral Interventions: Because the impairments associated with prenatal ethyl-alcohol exposure are timing and dose dependent, the FASD population is extremely heterogeneous. As a result, no single behavioral or educational intervention approach will meet the needs of all those in the FASD population. Interventions need to be designed to target the specific needs of a particular individual with FASD in order to be most effective. Indeed, targeted and multimodal interventions are reported to make important changes across behavioral and learning domains for children with FASD while also improving caregiver outcomes (Kalberg and Buckley 2007). Effectiveness may be maximized when interventions include a functional behavioral analysis to identify problem behaviors and antecedent events leading to those behaviors. This analysis can then be paired with caregiver and teacher education to “reframe” problem behaviors from a neurodevelopmental

perspective. Accommodations and environmental modifications to compensate for specific neurological deficits are also important pieces of any effective intervention program (c.f., Olson et al. 2005). Social skills training can be another important element in any comprehensive intervention plan and has been shown to be effective with school-age children with FASD. Targeted interventions for specific academic deficits are effective for children with FASD, and approaches that work with typically developing populations and children with other similar developmental disabilities should be effective interventions for individuals with FASD.

Fetal Anticonvulsant Syndrome

Usha Kini

Consultant Clinical Geneticist, Oxford Radcliffe Hospitals NHS Trust University of Oxford, Oxford, UK

Synonyms

Fetal antiepileptic drug syndrome (fetal AED syndrome); Fetal carbamazepine syndrome; Fetal phenytoin syndrome; Fetal valproate syndrome (FVS)

Short Description or Definition

“Fetal anticonvulsant syndrome” or “FACS” is the term used to describe the adverse effects of in utero exposure to anticonvulsant medication (e.g., phenobarbitone, phenytoin, carbamazepine, valproate, lamotrigine, etc.) and may manifest as dysmorphic facial features, major and minor structural anomalies, learning difficulties, and/or behavioral problems. Specific health and developmental problems are noted following exposure to specific antiepileptic drugs, e.g., phenytoin, valproate; the terms fetal phenytoin syndrome and fetal valproate syndrome are then used.

Epidemiology

Epilepsy is a common neurological condition affecting 0.6–1% of the population, and about a third of these are women of reproductive age. The majority of these women will be treated with antiepileptic drugs. Hence, approximately 1 in 160–250 pregnancies are exposed to antiepileptic drugs.

Phenobarbital was introduced for use as an antiepileptic drug (AED) in 1912, phenytoin in 1938, carbamazepine in 1961, and sodium valproate in 1964. In the early 1960s, there were reports from Germany (Janz and Fuchs 1964), followed shortly later by reports from England, describing a pattern of major and minor anomalies affecting orofacial, cardiac, and skeletal development in children with prenatal exposure to AEDs. Gradually, reports of cognitive deficits and behavioral problems emerged.

The exact incidence of fetal anticonvulsant syndrome (FACS) is not clear, as not all individuals with in utero exposure to AEDs show the adverse effects. Also, variability in the manifestation of the adverse effects is noted even between individuals who have been exposed to the same dose of the same AED. Some AEDs like valproate may be used in the treatment of neuropsychiatric disorders such as bipolar disorders. Offspring of these women are also at a risk of developing the adverse effects, if exposed in utero.

Natural History, Prognostic Factors, and Outcomes

Natural history: The diagnosis of FACS is first suspected when ultrasound scan abnormalities are identified in a pregnant woman taking AEDs. However, the absence of scan abnormalities is not reassuring, as minor structural abnormalities may not always be picked up on scan and also because the scans do not usually provide any clues to the neurodevelopmental problems that may develop later on in life.

The rate of obstetric complications in women with epilepsy is thought to be increased, but no single complication has been identified as a

Fetal Anticonvulsant Syndrome, Table 1 Congenital malformations associated with FACS

Systems involved	Abnormalities	Additional information
Neural tube defects	Spina bifida, anencephaly	1–2% risk of spina bifida with valproate, 0.5–1% with carbamazepine exposure
Congenital heart defects	Ventricular septal defects, atrial septal defects, patent ductus arteriosus	Seen with exposure to any AED
Orofacial clefts	Cleft lip and palate, cleft palate	Cleft palate has been reported with valproate exposure, but not cleft lip
Limb defects	Radial ray abnormalities, split hand malformation, polydactyly, tibial hypoplasia, camptodactyly	Seen with exposure to valproate; camptodactyly may be seen with other AED exposure as well
Genitourinary defects	Hypospadias, renal hypoplasia, hydronephrosis	More common with valproate exposure
Brain abnormalities	Agenesis of corpus callosum, porencephaly, hydranencephaly	Not frequently seen but have been reported
Eye abnormalities	Cataracts, optic nerve hypoplasia, iris defects	Iris defects have been reported with exposure to valproate only
Abdominal wall defects	Omphalocele	
Respiratory tract abnormalities	Laryngeal hypoplasia, abnormal lobation of lung, lung hypoplasia, tracheomalacia	More common with valproate exposure
Craniosynostosis	Trigonocephaly	Seen with valproate exposure only and is caused by premature fusion of the metopic suture; it may need surgical intervention

F

common finding, and in most studies, the increased rate of obstetric complications has not been found to be statistically significant. An increased incidence of stillbirths has been reported but not proven to be significant statistically. The birth weight is usually average. There is an increased rate of admission to special care baby units due to withdrawal symptoms such as lethargy, irritability, poor feeding, jitteriness, and due to the presence of major malformations such as neural tube defects, heart defects, kidney abnormalities, etc.

Congenital malformations: There is a 6–7% risk of structural abnormalities at birth compared to 2–3% in the general population. This risk may be as high as 9% in children exposed to valproate (Table 1).

Minor anomalies: Inguinal hernia, joint laxity, club feet, capillary hemangiomas (birth marks), strabismus (squint), nail hypoplasia, digital hypoplasia, clinodactyly, and overlapping toes are more frequently seen compared to the general population.

Facial dysmorphism: There are subtle facial features that are described with exposure to different AEDs. There is an overlap in the facial features described with exposure to different drugs. Of these, the facial gestalt of valproate exposure is the most characteristic and is formed by the following features: thin arched eyebrows with medial deficiency, epicanthic folds, infraorbital grooves, broad nasal bridge, short anteverted nose, smooth long philtrum, and a thin upper lip (Kini et al. 2006).

Childhood medical problems: Visual and hearing problems are more frequently seen. Myopia (short-sightedness) and squints are more common; hearing problems include recurrent otitis media with effusion.

Developmental delay and learning difficulties: Global developmental delay may be seen, but speech delay alone is more common. Joint laxity and poor muscle tone contribute to poor coordination which may affect daily activities such as writing, dressing and undressing, riding a bike, swimming, etc. A large proportion of children

have additional educational needs, and some of them may need one-to-one help much of the time (Adab et al. 2001). Many studies have shown that children exposed to AEDs such as carbamazepine, phenytoin, and even the newer drug, lamotrigine, have an IQ in the normal range (Gaily et al. 2004; Mawer et al. 2002; Dean et al. 2002; Meador et al. 2011). However, the verbal IQ of individuals with valproate exposure appears to be significantly lower (Adab et al. 2004).

Behavioral problems: Autistic spectrum disorders have been reported more frequently with valproate exposure (Rasalam et al. 2005). Difficulty in developing peer relationships, sharing interests and enjoyment, using language in social communication, symbolic or imaginative play, changes to routine, and lack of emotional or social reciprocity have been reported commonly. Poor concentration and hyperactivity are other behavioral issues reported.

Prognostic factors: Several factors influence the severity of FACS: (1) Type of AED – Valproate exposure causes the most severe adverse effects. (2) Number of AEDs – Polytherapy (exposure to more than one AED) has a worse outcome than exposure to monotherapy (one AED). (3) Dose of the drug – Although the adverse effects have not been found to be dose related with exposure to other AEDs, exposure to $\geq 1,000$ mg/day of valproate has been associated with more severe problems. Specific dose-related features of valproate are neural tube defects, radial ray abnormalities, obviously dysmorphic face, and a reduction in verbal IQ (Kini 2006). (4) Time of exposure – First trimester exposure is associated with structural abnormalities. It is possible however that AED exposure through the second and third trimesters may have an effect on neurodevelopment as the brain continues to grow throughout the pregnancy. (5) Parental and environmental factors – The child's IQ is known to strongly correlate with the parental IQ and also with the socioeconomic status. Women with epilepsy may themselves have learning difficulties, contributing further to the phenotype. (6) Genetic factors – The teratogenic effects of AEDs differ between fetuses that have been exposed to the same dose of the same drug suggesting that

maternal genetic factors may contribute. Studies have shown the contribution of genetic factors such as MTHFR (Kini et al. 2007), epoxide hydrolase genes, etc.

Clinical Expression and Pathophysiology

The clinical expression of FACS is very variable. The full spectrum of problems, i.e., dysmorphic facial features, major and minor malformations, developmental delay, childhood medical problems, learning difficulties, and behavioral problems, is rarely seen in a single individual with prenatal AED exposure. The presence of specific dysmorphic facial features may be a clue to early diagnosis. However, the facial gestalt is usually obvious in the most severely affected patients only. In fact, the facial features with exposure to some AEDs such as carbamazepine are very mild, adding to the difficulty of making a conclusive diagnosis. In addition, some individuals may present with subtle dysmorphic features and neurodevelopmental problems only. In these individuals, a diagnosis of “fetal anticonvulsant effects” should be considered.

Mechanisms of Teratogenicity

The exact mechanism by which AEDs cause their teratogenic effects is not known. Several plausible theories have been proposed:

1. Folic acid deficiency: AEDs such as phenytoin, phenobarbitone, and carbamazepine interfere with the intestinal absorption of folic acid, while valproate acts on its metabolism. Embryonic folic acid deficiency may disrupt gene expression, increase oxidative stress, and cause changes in protein synthesis (Wegner and Nau 1992). In animal studies, the rate of neural tube defects was reduced in mice exposed to valproate, when high doses of folic acid and folinic acid were given. Alteration in expression of folate pathway genes has been demonstrated in mice following valproate exposure (Finnell et al. 1997). Certain genetic

- polymorphisms in the folate pathway (*C677T* in the *MTHFR* gene) have been shown to be associated with a higher rate of malformations in AED-exposed children (Kini et al. 2007).
2. Oxidative stress: Intermediate metabolites of AEDs may increase oxidative stress in the developing embryo, whose antioxidant defense mechanism is immature. This may damage the developing organs of the embryo. Embryonic oxidative stress due to free radical formation following hypoxia from phenytoin-induced embryonic bradycardia has been demonstrated in animal studies.
 3. Arene oxide intermediates: Reactive intermediate metabolites of AEDs such as phenytoin and carbamazepine in the form of arene oxides may bind cell macromolecules affecting cell function and causing cell death. Arene oxides are detoxified by epoxide hydrolases; genetic variability in the activity of these enzymes may influence the susceptibility of the fetus to the adverse effects.
 4. Histone deacetylase inhibition: Valproate is a potent histone deacetylase inhibitor. Histone deacetylases are enzymes that induce chromatin changes to enable transcription of genes. Histone deacetylase inhibition therefore leads to interruption in the cell cycle, growth arrest, and apoptosis (cell death). Valproate also causes demethylation of DNA which results in changes in gene expression and hence in congenital malformations.

Evaluation and Differential Diagnosis

FACS is a difficult diagnosis to make as it is a diagnosis of exclusion. There are no specific tests by which the diagnosis of FACS can be confirmed. Hence, basic tests such as karyotyping, fragile X syndrome, and urine metabolic tests should be offered to the patients to rule out other causes. Other fetal insults such as exposure to alcohol, toluene, and maternal diabetes may cause similar features as FACS and should be kept in mind while taking the medical history. Malformations related to specific drug exposure such as radial ray defects and trigonocephaly with

valproate exposure may give a more definitive diagnosis, but other dysmorphic syndromes such as Baller-Gerold syndrome which have similar features need to be ruled out. This differentiation is important as it will impact on the recurrence risk given to these families. Referral to a clinical geneticist is therefore recommended. In those with a history of AED exposure, who present mainly with behavioral problems such as autistic spectrum disorder, evaluation for other syndromes such as Rett syndrome, tuberous sclerosis, and fragile X syndrome should be considered.

Treatment

Management

The management of FACS is symptomatic. Specific structural abnormalities, such as heart defects, kidney abnormalities, etc., may need monitoring, medication, or surgical intervention. Children with developmental delay may need help in the form of physiotherapy, speech and language therapy, and occupational therapy. Surveillance for childhood medical problems such as myopia and recurrent otitis media is recommended. Assessment for special educational needs should be carried out early and appropriate help instituted early to allow the child to develop to his or her full potential. Behavioral therapy and sometimes medication may be helpful in dealing with behavioral issues such as autistic spectrum disorder and attention deficit/hyperactivity disorder.

Prevention

For women with epilepsy, prepregnancy counseling should be provided so as to reduce the risk of FACS. Every attempt should be made to reduce the dose (e.g., valproate should be reduced to <1,000 mg/day) and number of AEDs to the minimal level required to control the epilepsy, and this should be done in liaison with the neurologist. Monotherapy is preferable to polytherapy. Valproate should be avoided wherever possible as this has been deemed to be the most teratogenic AED (Mawer et al. 2002). The weaning of the AED should be done well in advance of the pregnancy as seizures during

pregnancy may have a detrimental effect on the health of the mother and baby.

High-dose folic acid (4–5 mg/day) is recommended during pregnancy, starting from at least 6 weeks prior to conception. While intake of folic acid in the first trimester may help prevent congenital malformations, intake in the last two trimesters may help prevent neurodevelopmental problems due to continued development of the fetal brain throughout pregnancy. Antenatal scans should be offered at about 12 weeks (gross structural abnormalities such as anencephaly can be identified) and a detailed anomaly scan should be offered at 18–20 weeks. Malformation such as isolated cleft palate is likely to be missed on antenatal scans.

Figurative Language

Maura Moyle and Claire Plowgian
 Speech Pathology and Audiology, Marquette
 University, Milwaukee, WI, USA

Synonyms

[Figures of speech](#); [Metaphoric language](#); [Non-literal language](#)

Definition

Figurative language is language that is used in nonliteral ways in order to achieve a special effect or meaning. Similes, metaphors, idioms, proverbs, and slang are examples of figurative language. The ability to comprehend and produce nonliteral language is an important development in school-age children. Figurative language is commonly used in a variety of communicative contexts, including casual conversation, teacher talk, and written texts.

Individuals with autism spectrum disorders (ASD) often have difficulty comprehending figurative language and may interpret figurative statements literally. Upon hearing the expression “It’s raining cats and dogs,” an individual with ASD may think that the speaker means that cats and dogs are literally falling from the sky. The meaning

and appropriate use of figurative language may need to be explicitly taught to individuals with ASD. Difficulties with figurative language are common in individuals with a variety of disorders (e.g., Specific Language Impairment, Attention Deficit Hyperactivity Disorder).

Figure-Ground Discrimination

Francesca Happé
 MRC Social, Genetic and Developmental
 Psychiatry Centre, Institute of Psychiatry,
 Psychology and Neuroscience, King’s College
 London, London, UK

Definition

Figure-ground discrimination or perception refers to the ability to separate the elements of a visual image on the basis of contrast (e.g., light, dark), to perceive an object (figure) against a background (ground). A classic illustration of figure-ground perception is the Rubin vase, a simple black and white image which can be seen as two dark faces against a white background, or a white vase against a dark background. As well as simple properties, such as light and dark, more complex gestalt properties help separate the important objects in a scene from the background. The ability to discriminate

figure from ground can also refer to the more general capacity to tell foreground from background information, or identify what is important versus what is less salient.

In ASD, superior ability is seen in some tasks requiring identification of parts within wholes, such as the Embedded Figures Task (see entry). This has been interpreted within theories postulating a detail-focused cognitive style in ASD, such as the “weak central coherence” account. Ambiguous figures (e.g., duck/rabbit), of which the Rubin vase may be considered an example, have been used in autism research to investigate flexibility (see ► [“Behavior Observation Scale”](#)) and also self-awareness. Findings are mixed; whether people with ASD show neurotypical patterns of processing ambiguous figures depends in part on whether this is tapped through explicit or implicit tasks (e.g., Allen and Chambers 2011). Links have also been found between ASD-like *traits* and the perception of multiple interpretations of ambiguous figures, perhaps reflecting figure-ground discrimination processes (Best et al. 2008).

Fine Motor Development

Jane Case-Smith

Division of Occupational Therapy, School of Health and Rehabilitation Sciences, Columbus, OH, USA

Definition

Fine motor skills are also termed hand skills, fine motor coordination, object manipulation, or dexterity. Components of fine motor development include reach, grasp, release, in-hand manipulation, and bimanual coordination (Exner 2010). Early development of these skills requires integration of the visual motor and somatosensory systems. Fine motor skills initially develop through the infant’s sensory motor exploration, e.g., the infant’s reach and grasp of objects. They are refined as the young child develops functional and pretend play skills that include manipulation, eye-hand coordination, and bimanual skill. In older children and adults, fine motor development involves learning the precise, complex sequences of movement required to perform writing, keyboarding, activities of daily living, leisure pursuits, and vocational tasks. Delays or disorders in fine motor development can relate to low muscle tone or poor strength; impairment in visual motor skills, bimanual coordination, or precision of manipulation (dexterity); and motor learning deficits or dyspraxia (motor planning problems).

Historical Background

In the past, researchers and practitioners did not broadly recognize that children with ASD have impaired fine motor development. The few studies that included motor development noted that motor

skills were a strength in some children, particularly when compared to cognitive and communication skills (Gillberg et al. 1990; Mayes and Calhoun 2003). Using parent report of motor development, Mayes and Calhoun found that 67% of their sample with ASD had normal motor milestones. Early research highlighted the exceptional manipulation skills of certain individuals with ASD, e.g., savants (Hermelin et al. 1994).

Contributing to the confusion about whether or not children with ASD have fine motor impairment, a number of studies found that the motor development of children with ASD was similar to that of children with general developmental delay (Provost et al. 2007), learning disabilities (Miyahara et al. 1997), or language delays (Landa and Garrett-Mayer 2006). One interpretation of these findings is that fine motor delays may reflect general developmental disability rather than define a core feature of ASD. More recent literature confirms that fine motor impairments are not only prevalent in ASD but are long lasting and persistent, affecting function throughout the lifespan (Vanvuchelen et al. 2011).

Current Knowledge

Prevalence

Recent studies and systematic reviews have estimated the extent and prevalence of fine motor delay and motor coordination impairment in children with ASD. Ming, Brimacombe, and Wagner (2007) found high prevalence of motor impairment in a cohort of 154 children with ASD. In young children 2–6 years, 63% exhibited hypotonia, and in children 7–18 years, 38% exhibited hypotonia. Motor planning problems, i.e., Dyspraxia were common (34%) in this cohort.

When prevalence was examined using clinical data from standardized motor development scales, 63–68% of a sample of children with ASD had significant motor delays of more than 25% (Provost et al. 2007). Eighty-four percent of the children demonstrated at moderate fine motor delays. Although the fine motor skills of the young children in this sample were significantly

lower than the typical children and the normative sample, their performance was similar to a comparison sample of children with developmental disabilities. This finding that motor skill development of children with ASD is similar to children with other developmental disabilities is consistent across studies (e.g., Bhat et al. 2011; Landa and Garrett-Mayer 2006).

Using rigorous meta-analysis techniques with 83 studies of motor coordination in ASD, Fournier, Hass, Naik, Lodha, and Cauraugh (2010) examined 51 comparisons of children with ASD to typically developing peers. The standardized mean difference in motor coordination was substantial with an average effect size of 1.2. Given these robust findings, Fournier et al. (2010) concluded that motor coordination deficits are a cardinal feature of ASD.

Infants and Young Children

Beginning in the late 1990s, researchers who analyzed videotapes of infants later diagnosed with ASD reported that the infants showed fine motor differences and stereotypic arm movements (Adrien et al. 1993; Baranek 1999). These retrospective studies revealed that at young ages, children exhibit deficits in specific movement patterns, hypotonia, hypoactivity, and aberrant motor patterns. These retrospective studies motivated researchers to complete prospective studies to examine fine motor skills in young children at risk for ASD (Bryson et al. 2007; Gernsbacher et al. 2008; Landa and Garrett-Mayer 2006).

Prospective studies of infants and toddlers at risk for ASD suggest that motor characteristics may provide a reliable early sign of ASD. When compared to the manual skills of a typically developing sample, those of children later diagnosed with ASD were significantly delayed (Gernsbacher et al. 2008). At 6 months, the infants were less skilled in reaching and grasping of objects, and at 12 months, they were significantly less skilled in stacking, scribbling, and banging. At 18 and 24 months, the toddlers were deficit in the fine motor skills important to communication (pointing) and play (using puzzles and blocks). Although this study identified motor delays in the youngest age groups (6 and 12 months), other

studies have reported that significant differences in fine motor skills among children with ASD do not emerge until 14 months (Landa and Garrett-Mayer 2006). As an early sign of ASD, motor delays or atypical movement patterns can contribute to its early identification.

In preschool age children, 3–4 years, Jasmin et al. (2009) found that 53% had fine motor delays. The mean fine motor composite score and mean scaled scores for the children with ASD were below the normal range, suggesting moderate fine motor impairment. These studies conclude that young children with ASD exhibit mild to moderate delays in fine motor skill and estimate that between 53% and 84% of all children with ASD have fine motor delays or problems.

Based on the assumption that movements (e.g., gestures, oral motor skills, motor imitation) are fundamental to social interaction, researchers (Bhat et al. 2011) suggest that motor impairments may negatively influence children's acquisition of social and communication skills. The correlation of fine motor skills to development of social interaction and communication proficiency needs to be further researched to confirm or refute this hypothesis.

Older Children and Adolescents

Older children and adults with ASD, 7–32 years, have shown impairment in visual motor and manual dexterity tasks (Bhat et al. 2011; Green et al. 2002). When fine motor skills of older children with ASD were compared to children with learning disabilities (LD), they were lower in manual dexterity such as manipulation, drawing, and cutting (Miyahara et al. 1997). Manjiviona and Prior (1995) found that children, 7–17 years with Asperger's syndrome (AS) and high-functioning autism (HFA), demonstrated motor impairment in manual dexterity, including speed and accuracy of hand movement, eye-hand coordination, and bimanual coordination. They also demonstrated more movement errors. Hilton et al. (2007) found that children with Asperger's syndrome scored below the mean on a standardized assessment of motor skill. These findings are consistent with others who found a slower reaction time in

skilled motor tasks (Mostofsky et al. 2000). They suggest that children with AS and HFA have difficulty with motor learning and motor planning.

Children with ASD often demonstrate poor handwriting legibility. When children with ASD were compared to typically developing children on a standardized handwriting assessment, the children with ASD had significantly lower legibility. Specifically, they showed impairments in forming letters, leading to lower overall quality and legibility (Fuentes et al. 2009). One contributing factor to learning legible handwriting is using a consistent preferred hand to write. Frequently, children with ASD are delayed in establishing hand dominance and show mixed laterality or left-hand dominance. Hauck and Dewey (2001) found that children with ASD often do not establish hand dominance and that this lack of preference was not related to cognitive level or lack of motor skills. Studies from the 1980s found that 22–36% of children with ASD do not show a hand preference at ages that hand dominance should be established.

These studies suggest that precision of manipulation, quality of movement, and movement speed are lower in older children with ASD, and these differences can occur in children across the spectrum. The research literature suggests that the majority of children with ASD have significant motor delays or deficits and that these deficits can limit daily living skills, play, communication, and peer interaction.

Motor Imitation

Motor imitation is fundamental to learning and is important to both social and cognitive development (McDuffie et al. 2007). Motor skills are also learned, in part, through a child's imitation of others, i.e., attending to another person's movement and then repeating that movement. The child's goal may be social interaction or may be self-motivated imitation and mastery. Children with ASD have impairments in imitation that are believed to be core to their social impairment (Rogers et al. 2003; Stone et al. 1997). Because these children imitate less, they may have less practice of age-appropriate motor skills. On the

other hand, fine motor delays may be a reason that children exhibit limited motor imitation. When a sample of children with Asperger's syndrome (AS) were compared to a matched sample of children with developmental motor delays, the children with AS had difficulty imitating gestures, particularly when the gesture required symbolic representation of an object (Green et al. 2002). Motor performance using a standardized test accounted for 45% of the variance in imitation performance.

In further investigation of motor imitation, Vanvuchelen, Roeyers, and deWeerd (2011) reported that boys with ASD had problems in motor imitation, whether or not they had cognitive impairment. They concluded that the motor imitation problems were more related to general motor competence than executive function. McDuffie et al. (2007) examined the correlates of motor imitation in children with ASD. They investigated the relationship of attention-following and nonimitative fine motor ability to motor imitation. Both fine motor ability and attention-following accounted for unique variance in motor imitation performance. Whether impaired imitation is a cause or result of lower fine motor skill, it likely relates to and influences fine motor development. Mostofsky et al. (2006) further clarified that motor imitation appears to be delayed but not disordered in children with ASD. Therefore, the delay in acquisition can catch up during late childhood. Previously reported cross-sectional studies of motor development noted that motor delays are common in young children with ASD and less prevalent in older children.

Motor Planning

Motor planning or praxis is the ability to plan and sequence novel or unpracticed movements to reach a goal. A number of studies have identified apraxia or motor planning problems in children with ASD. Using kinematic analysis for reaching, Forti et al. (2011) found that children with ASD were slower in planning their movements and needed to reorient their hand as they reached toward a target. They required more self corrections to accurately reach the target, indicating less automaticity and slower processing. These

findings concur with Rinehart et al. (2001) who found that children with ASD are slow to prepare movement and have impaired anticipatory guidance.

When children with ASD were tested specifically on praxis, e.g., using gestures and tools, they made significantly more errors than children who were typically developing (Mostofsky et al. 2006). This study confirmed earlier findings that high-functioning children with ASD have impaired performance of gestures and problems in motor planning of precise movements (Rogers et al. 1986). Motor planning deficits appear to relate to perception of kinesthetic/spatial aspects of movement (i.e., sensory feedback) and planning of goal-directed actions (Mostofsky et al. 2006). These authors concluded that children with ASD can have deficits in conceptual planning or learning of movement.

Praxis problems or dyspraxia implies that a child has a distinct impairment in planning movement that cannot be accounted for by impaired motor execution or a general movement disorder. To analyze if children with ASD have basic motor skill deficits or dyspraxia, Dziuk et al. (2007) measured performance on a praxis test and on a basic motor skill assessment in a sample of children with ASD, aged 8–14 years. They found that basic motor skill had a significant effect on praxis performance. Although basic motor skills and dyspraxia in ASD were related, the dyspraxia could not be entirely accounted for by basic motor skill deficits. These authors concur with Mostofsky et al. (2006) that praxis deficits in ASD relate to children's perception of sensory feedback from movement, spatial representation of movement, and ability to learn movement.

Stereotypic Movements

In addition to motor delays and motor planning problems, children with ASD may exhibit abnormal movement or motor stereotypies. These include arm flapping or finger flicking and are characterized as repetitive, seemingly non-purposeful movements (Bhat et al. 2011). Retrospective studies of children with ASD have found that toddlers exhibit atypical hand and finger movements and more stereotypical object play,

such as spinning objects. These repetitive movements may interfere with motor development or may create a propensity for stereotypic movements through adulthood (Matson et al. 2009). These motor stereotypies are believed to relate to sensory processing and may serve to lower or raise arousal.

Repetitive movements are also associated with lower levels of overall functioning. Cuccaro et al. (2003) found that children use stereotypic movements for sensory stimulation or as an adaptive function to cope with transitions or changes in the environment. In general, stereotypic movements appear to decrease with age. When useful to support a person's arousal level or ability to cope, stereotypic or repetitive movements may serve an adaptive, functional purpose.

Summary

Fine motor skills are fundamental to social skills and communication and are an important consideration when remediating the core deficits of ASD. A majority of children with ASD have delays in fine motor development, and motor impairments tend to continue through adulthood (Fournier et al. 2010). Fine motor delays are more apparent in young children than in older children, suggesting that motor learning is a factor. Although the severity and prevalence of fine motor deficits appear to improve as children with ASD reach adulthood, motor coordination and motor planning impairments persist.

Fine motor development is among the variables that significantly influence function in children with ASD. Underlying motor delays can impair a child's ability to gesture, imitate, manipulate toys, and participate in social play. In older children, motor planning and motor coordination problems can relate to poor handwriting, school difficulties, and limited participation in sports and recreation. In adults, the fine motor deficits can restrict vocation or leisure pursuits. Researchers recommend that comprehensive intervention programs for persons with ASD include specific strategies to improve fine motor skills (Bhat et al. 2011; Fournier et al. 2010).

Future Directions

Recent studies of children and adolescents with ASD suggest that they present with motor learning and motor planning impairments. It is not clear how the fine motor and motor coordination impairments relate to the cognitive features of ASD. Research is needed to better understand motor skill development and to further analyze how imitation, praxis, and motor learning influence fine motor performance.

With increased understanding of the basis for fine motor deficits, specific interventions can be designed. Efficacy research on motor skill interventions for ASD is scant (see Baranek 2002), and rigorous trials are needed.

Dallas, TX, USA

Synonyms

[Finger oscillation test](#); [FOT](#); [FTT](#)

Definition

The finger-tapping test (FTT) is a neuropsychological test that examines motor functioning, specifically, motor speed and lateralized coordination. During administration, the subject's palm should be immobile and flat on the board, with fingers extended, and the index finger placed on the counting device. One hand at a time, subjects tap their index finger on the lever as quickly as possible within a 10-s time interval, in order to

increase the number on the counting device with each tap. The original procedure calls for five consecutive trials within a 5-point range for each hand, but variations include a total of six trials, in two sets of three. Results from FTT can be compared to age and gender normative data and may indicate motor impairment or lateralized brain dysfunction. The FTT is included in the Halstead-Reitan neuropsychological test battery.

The FTT may be included as part of a comprehensive neuropsychological assessment for children with Autism Spectrum Disorder. Additionally, the FTT has been used in multiple research protocols as a standardized method for assessing motor speed as it relates to brain functioning and anatomy.

Definition

This entry is focused on providing: (1) background on contact between autistic individuals and the criminal justice system and (2) guidance to first responders on issues that may arise in a first contact situation involving an autistic person to enhance their ability to act in an autism-friendly manner.

Historical Background

Although research in this area is limited, there is some evidence to suggest that autistic individuals come into contact with the criminal justice system significantly more often than predominant neurotype (PNT; nonautistic) individuals (King and Murphy 2014). Although autistic people are statistically less disposed to criminality (Mouridsen et al. 2007), they are seven times more likely to be arrested (Curry et al. 1993), sometimes unlawfully. The longer they remain (innocently) in the criminal justice system, the greater the injustice and suffering inflicted upon them. There are also potential negative impacts on the police such as a greater risk of litigation, waste of resources, and negative public relations. There is a clear need for the police, and, in particular,

officers initially on the scene of an incident (first responders), to have a sufficient understanding of autism, how it may present in an individual, and how best to handle incidents involving an autistic person.

So what is autism? Richard Howlin (2003) calls it social dyslexia. In the same way that dyslexia involves difficulty understanding words, the term “social dyslexia” captures the difficulty that all autistic individuals have, to a greater or lesser degree, in understanding social situations. As virtually all situations people find themselves in are social, not fully understanding social behavior can give rise to problems when interacting with other people including first responders. Autism is highly complex for various reasons. Firstly, there is its heterogeneity and extreme diversity whereby one autistic individual is unable to live independently or work whereas another highly intelligent individual is married and working as a university professor. Although the variation in presentation in autism is very wide, all autistic people will have difficulties in understanding PNT social behavior. Autism may also involve what are known as repetitive behaviors (beneficial to the person by introducing some stability and/or being comforting) and “special interests” (fewer, more intense interests than is usually the case for the PNT). Many autistic individuals are hyper- and/or hyposensitive to sensory stimuli (Bogdashina 2016). Many individuals also experience debilitating anxiety (Bejerot et al. 2014). Autism is made even more complex as the majority of autistic individuals have other conditions as well as autism (comorbidities). These may include pathological anxiety, clinical depression, attention-deficit hyperactivity disorder, and obsessive-compulsive disorder (psychiatric comorbidities), and allergies, gastrointestinal problems, migraines, and seizures (medical comorbidities).

Yet another complexity in autism is the ever-changing diagnostic criteria. For many years to come, any of the following diagnoses may come to the attention of first responders: Asperger’s disorder, Asperger’s syndrome, atypical autism, autism spectrum disorder (ASD), “classical” autism, and pervasive developmental disorder not otherwise specified. All first responders need

to know is that these are all attempts by clinicians to diagnose autism so if they are informed that a person they are involved with has one of these diagnoses they know that autism is involved and must respond accordingly.

If an officer is advised by their despatcher that an individual is autistic, or the individual themselves discloses their autism, any interaction requires sensitive handling based on an understanding of autism. In the introduction to his field response tips for first responders encountering a person with autism, Debbaudt writes: "Law enforcement professionals may unexpectedly encounter or be asked to find a person with autism. Recognizing the behavior symptoms and knowing contact approaches can minimize situations of risk - risk or victimization of the person with autism, and risk to the officer" (<http://www.autismriskmanagement.com/autism-articles>). The role of police officers and other emergency service personnel in a first response situation is to avoid a situation where lack of knowledge of autism causes a situation to escalate beyond what would be expected because of a failure to understand autism. The training of all first responders in autism (and other neurodiverse conditions) is therefore essential.

Current Knowledge

Autistic people are in contact with the police as victims, witnesses, and perpetrators. In this respect, they are no different from people without autism. The differences could arise in various ways. Firstly, while contact with law enforcement can be a stressful thing for anyone, people with autism – who tend to experience greater levels of anxiety, and have lower levels of "global stability" (strategies to cope with the "ups and downs" of life reasonably easily) than their PNT peers – are likely to find such contact especially stressful (Beardon 2008; Chown 2010; Debbaudt and Rothman 2001; North et al. 2008). Secondly, there is an ongoing debate as to whether or not persons with autism are less likely to commit crime than those without autism because of the general tendency in autism to comply with rules

and/or are particularly prone to committing certain types of crime (e.g., stalking) because of social difficulties and less well-developed theory of mind (the means by which people make sense of the behavior of others by attributing beliefs, desires, and feelings that motivate actions) than the PNT (King and Murphy 2014).

On the issue of whether autistic people are more or less likely to commit crimes than their PNT peers, Mouridsen (2012) concluded that:

Currently, there is still no body of evidence to suppose that people with ASD are more prone to commit offences than anyone else. However, a small number of serious crimes can be linked to the core features of ASD. Co-morbid psychiatric disorders are important risk factors for offending in people with ASD. (Mouridsen 2012, p. 79)

Although Mouridsen is careful to clarify that there is no valid evidence regarding types of offending that may be associated with autism, he discusses certain types of offending that the limited studies undertaken in this area indicate *may* be linked with autism. The serious crimes he referred to are arson and sexual offending with and without violence. He concluded by repeating that "available findings still indicate that people with ASD are not more prone to committing offences than anyone else" (ibid., p. 85).

Since Mouridsen's review, Sevillever et al. (2013) have reported on sexual abuse and offending in autism. They have been unable to identify any evidence of a greater risk of sexual offending conduct in autistic individuals. They include a useful discussion of factors that may lead to an increased or reduced risk of sexual offending in autism (summarized in the following table) that may be of more general application.

Factors that may increase the risk

Difficulty with social-emotional reciprocity/reduced levels of empathy (PNT individuals who sexually offend also demonstrate lack of empathy for their victims)

Naiveté (interpersonal/exploitation by others)

Sexual frustration and preoccupations/limited intimate relationships

Comorbid intellectual disability (in which case it may be the latter that increases the risk of offending)

Individuals with autism may be more likely to offend against younger children because, given poor social

(continued)

skills, younger children may be easier to interact with than older children or adults

Tendency to engage in private sexual behaviors in public places

Factors that may decrease the risk

The greater supervision of some autistic individuals reducing opportunities to offend

A limited ability to deceive others which may reduce precursor behaviors to sexual offending

A tendency for autistic individuals, especially higher functioning individuals, to be rule-governed could inhibit such offending

Extracted from Sevelever et al. (2013), pp. 192 and 194–195

Where there is a comorbid psychiatric disorder in addition to autism, one has to bear in mind that it may be the comorbidity that is leading to the offending acts, not the autism per se. We know of no research suggesting that an autistic person with any particular comorbid psychiatric disorder is any more likely to commit a crime than a PNT individual with the same psychiatric disorder. Based on their systematic review of the literature, King and Murphy (2014) reported that there was “little” evidence to support the often-heard contention that people with autism are overrepresented in relation to certain crime types. Allen et al. (2008, p. 748) expressed the view that “The apparent association with offending has been in part generated by sensationalised ... media reports.” As some autistic individuals who commit a crime do so without criminal intent, there may be a lower tendency to *knowingly* commit crimes in autism (Beardon 2008).

Autistic individuals are well known to have uneven ability and skills profiles. While a person may be extremely adept in one area, they may present as extremely poor in another. This can lead to erroneous assumptions being made by others – either of ability above and beyond actual capability or incorrectly inferring a skill set is below par. Having an “autism profile” that identifies how autism impacts on an individual on a day-to-day basis can be an invaluable tool to help understand experience from that autistic person’s perspective. It is extremely common for people to make judgments based on behavior, and it is equally common for those judgements to be based on years of ingrained PNT concepts; however, the

application of those judgements onto an autistic person whose behavior results from different cognition is likely to lead to false premises. A good autism profile must include a full sensory profile, i.e., a thorough identification of how the sensory environment impacts on the individual.

Anxiety and poor stress management are common in children with autism. Anxiety levels may increase during adolescence, as young people face an increasingly complicated social environment and often become more aware of their difficulties interacting with others (White et al. 2009). Anxiety levels exhibited by adolescents with autism are significantly higher than those in the general population. Anxiety remains a serious issue for many adults with autism. Gillott and Standen (2007) demonstrated that adults with autism were almost three times more anxious than their comparison group of adults with intellectual disabilities. They wrote that “stress was found to correlate with high anxiety levels for the autism group, particularly the ability to cope with *change, anticipation, sensory stimuli and unpleasant events*” (ibid., 2007, p. 359, *our italics*). While a first response situation, or other contact with the criminal justice system, is likely to be stressful for most people, individuals with autism will often face higher levels of anxiety and stress than their PNT peers. Steps should be taken, as far as possible, to reduce anxiety and stress; this will be of benefit to first responders as well as to the autistic individuals. We have set out various steps that can be taken in a variety of situations to achieve this. However, the most important action an organization can take is to train its officers, and those staff who come into contact with the public, to have an understanding of autism.

The behavior of an autistic individual at times of duress is highly likely to differ from that of a PNT individual. If that behavior is only understood within a PNT context, it is very probable that it will be misinterpreted. At times of increased anxiety, the individual may well present behaviors necessary to avoid a “meltdown.” Many autistic people experience meltdowns. The public often finds it hard to tell meltdowns and temper tantrums apart, but they are different things. A meltdown is an intense response to a situation

an autistic person finds overwhelming. To cope with such a situation, the autistic person may need to engage in repetitive body movements (stimming). Interrupting this may increase levels of anxiety exacerbating the situation. Some possible scenarios that could lead to incorrect initial perceptions on the part of first responders include:

1. *Refusal to engage* – Sometimes, when under duress, the autistic response is essentially to shut off from external stimuli as much as is possible. To the “untrained eye,” the person may appear to be refusing to respond, or excessively rude, or even having something physically wrong with them. But it may be a coping mechanism to reduce their anxiety.
2. *Seemingly excessive reaction to proximity and/or touch* – At times of high anxiety, sensory sensitivities may be greatly increased. This means that if someone is tactile sensitive, for example, then any touch (including very light touch) may be processed as intense pain. In some cases, a “natural” reaction to a perceived assault for some people would be to defend themselves. Even well-intentioned contact meant as reassurance might be perceived as painful. Sometimes an autistic individual can move from a state of anxiety to a state of panic simply because someone such as a first responder is too close to them.
3. *Already in a state of panic* – A single-crewed officer received a call about a man with a knife. She followed the man in her car to allow backup to arrive but soon realized that she knew the man to be autistic and with intellectual learning difficulties and that he was not dangerous. A group of young men had approached him and sent him into a panic. The officer knew that firearms officers and dogs were on the way to the scene, so she knew she had to act quickly and get the knife off him. She explained that other officers would soon arrive who did not know him like she did and was able to get him to throw the knife away. She also agreed not to handcuff him, as she knew it would hurt him, and suggested that they sat in the back of the police car together. The situation had been “defused.”
4. *Eye contact issues* – Social practice assumes a good way of gaining attention is to insist on eye contact and that eye contact reciprocity will lead to a greater sense of trust. Although some autistic people do not have difficulty looking other people in the eye, many do and this difficulty can be exacerbated at times of stress. A first responding police officer may easily misinterpret this as deliberate evasion, a guilty reaction, or disrespect. Of course, as with any other individual, an autistic person can deliberately evade, react guiltily, or show disrespect, but it is far more likely that not looking the officer in the eye is an aspect of their autism.
5. *Flight risk* – A person with autism may try and run away from a situation involving a first responder. Unless an officer has an understanding of autism, they will assume that this is a guilty reaction. It could be a guilty reaction of course but the officer should not assume this as it may be an autistic reaction. The autistic person may have great difficulty with social interaction and experience high levels of anxiety. Their natural response may be to get away from a highly stressful situation without thought as to the impression this creates, nor to the potential consequences of their own actions.

There are other aspects of autism that may lead to misinterpretation of behavior by first responders irrespective of an autistic individual’s level of anxiety. For example:

6. *Sensory processing* – Autistic individuals may only be able to process sensory information through one sensory channel at a time. This is known as single attention (Murray et al. 2005). They may be unable to process auditory information, for example, because they are focusing on visual information. A lack of ability to hear, and subsequently respond to, verbal requests may come across as defiance and/or noncompliance.
7. *Shutdown* – A shutdown is caused by the same factors that cause a meltdown but instead of losing behavioral control the individual stops

reacting to the situation as a means of avoiding it. An autistic former member of the police staff of a major United Kingdom police force found herself in the reception area of an office building when police suspected a terrorist incident was in play. An officer shouted to the people there to get out of the building. This autistic individual “froze.” This was misinterpreted by officers and a difficult situation arose.

8. *Lack of or “odd” facial expression/nonverbal communication* – Some autistic people demonstrate either no facial expression (i.e., the “same” face irrespective of the situation) or a facial expression seemingly at odds with the situation (e.g., smiling when in distress). The misinterpretation of facial expressions could put the autistic individual at risk. First responders should be aware that facial expressions, “body language,” and other nonverbal cues are not always an indication of an emotional state or intent.
9. *Expressive versus receptive language* – For most people, expressive language skills are a reasonable indicator of receptive skills (comprehension). In other words, there might be an assumption that an eloquent person will have equally good comprehension skills. This may not be the case with an autistic person who may display very good expressive language skills but have huge problems with understanding what is being said to them; conversely, they may not speak but have a good understanding when being spoken to.
10. *Feeling obliged to respond* – Remaining with the poor comprehension theme, some individuals will have learnt (usually by being directly taught) that a rule in verbal exchanges is that they *must* respond if asked a question. This places the individual at a huge disadvantage if they feel obliged to respond despite not understanding the question. In an interview situation, this clearly could create numerous problems for an autistic individual.
11. *Difficulty with repeated questions* – An autistic individual may consider that once they have responded to a question that should be the end of that particular matter as they have said what they wanted to say in response and should not be expected to answer the same question again. This may present a problem for officers in a police interview situation where standard interviewing technique may require repetition of certain questions. Officers should be aware that refusal to answer a repeated question may not reflect lack of cooperation.
12. *Multiple concepts or questions at one time* – Many autistic people can get confused when they are asked to deliberate over multiple concepts at the same time or when more than one question is asked at the same time. It is good practice when communicating with an autistic person to ask questions that are clear and “one dimensional” and to do so one at a time.
13. *Literal interpretation* – An autistic person often has a very specific way of understanding language. They may assume a direct correlation between the words being spoken and their meaning (sometimes referred to as literal interpretation). However, many people do not use language in this way, even if they might think they do. Language is full of contradictions and ambiguities and some people’s use of language is more accurate than others. For example, the instructions: “Freeze! Don’t move! Take your hands out your pockets and turn around slowly...” have a clear meaning for most people. But to an autistic person in a stressful situation, it might appear that the person is quite literally contradicting himself or herself and they will not know how to react to what they hear as a confusing set of commands.
14. *Processing language* – Processing time may be considerably longer for autistic individuals than for PNT individuals. This means that after each sentence, for example, an individual might need a few seconds to “digest” what has been said in order to understand it. If this additional processing time is not allowed,

either the person will fall further and further behind the communication – or they will simply miss chunks of it out in order to keep up.

15. *Prosody* – this refers to the tone of voice, inflection, and stressors placed on words – which is often either misunderstood or not taken into account at all by an autistic person. In some cases, the same sentence can have very different meanings dependent on the prosodic expression – in written language grammar along with italics provides the equivalent information. It is important for anyone communicating with an autistic person to take into account that their language (including prosody) needs to be as ambiguity-free as possible. For example, asking “*what* do you think happened” may mean something very different to “what do *you* think happened,” but the prosodic inflection may not be processed by the autistic person.

Some autistic people may break the law as a direct result of the way in which autism impacts upon them, as opposed to having criminal intent (Beardon 2008). Having an understanding of what caused an autistic person to behave in a criminal manner would enable better decisions. For example, an autistic adult who is both socially naïve and desperate for friendship might be persuaded to hoard stolen goods in return for the promise of being included in a social group. Lack of understanding of cause and effect, consequences of actions, difficulty with understanding the intentions of others, naïve levels of trust, difficulty in reading social situations, and accepting language at “face value” are all common characteristics of being autistic and may increase the risk of engaging in activity without knowing that it is criminal activity.

Future Directions

In this section, we discuss the importance of disclosure of a diagnosis of autism, include tips for first responders in a “first contact” situation (courtesy of the autism specialist, Dennis Debbaudt) and for communicating with persons

with autism (including in an interview situation), make some general comments on anxiety levels and sensory sensitivities in autism, and include recommendations for future practice.

Police officers and other first responders come into contact with all types of neurodiversity, not just autism. While clinicians often require hours to diagnose a neurodiverse condition, first responders may have very little time in which to “size up” an individual with whom they are in contact. Even if all first responders received effective training in neurodiverse conditions, they cannot be expected to identify any one of these conditions in a first response situation. This emphasizes the importance of disclosure in such situations. It is appreciated that there are various reasons why an individual may not wish to disclose a diagnosis outside family and friends. However, we consider it important that police forces, other first response organizations, and those advocating for autism and other neurodiverse conditions do all they can to encourage disclosure in first response situations (even by those individuals who otherwise would not disclose) as first responders cannot reasonably be expected to react appropriately in every situation they may face in the absence of disclosure.

Major autism charities in the United Kingdom, like the National Autistic Society, have produced information cards that autistic people can carry and share with first responders. These cards explain that the person they are speaking to is autistic. They also highlight the potential of communication difficulties the autistic person may have during unfamiliar situations. Debbaudt (2002) has developed some guidelines to assist first responders when an individual is known to be autistic.

- Approach in a quiet, nonthreatening manner.
- Turn sirens and flashing lights off.
- Talk calmly in a moderated voice.
- Do not interpret limited eye contact as deceit or disrespect.
- Avoid metaphorical questions that cause confusion when taken literally.
- Avoid body language that can cause confusion. Be alert to a person modelling your body language.

- Understand the need to repeat and rephrase questions.
- Understand that communications will take longer to establish.
- Use simple and direct instructions and allow for delayed responses to questions, directions and commands (Debbaudt 2002).

We would add the following additional guidance to Debbaudt's suggestions:

- Where possible avoid touch as even a light touch may cause pain where a person is hypersensitive. Touching may cause a "flight or fright" reaction; don't assume that means the person is guilty of an offence.
- The cold metal part of handcuffs may cause pain so avoid where possible.

When a person is arrested they are being deprived of their liberty and an officer needs to explain why, in the form of a police caution. The police caution can be complicated to understand so instead of asking a suspect if they understand which may produce a "yes" or "no" response, ask them to explain in their own words what they understood; this could help to identify vulnerable suspects. It is worth noting that in the UK, the Police and Criminal Evidence Act, 1984 (PACE), states that a person should be treated as vulnerable when a custody officer has any doubt about their mental state. Easy read custody sheets that help bridge the gap between a custody officer and a suspect whilst they await an appropriate adult have been piloted in a UK force with positive outcomes for autistic people. Moreover, they take away the uncertainty of what will happen while they are in custody (Parsons and Sherwood 2016).

Attwood (2008) suggests that a number of autistic people find that sensory sensitivity causes them more issues in daily life than the social aspects connected with autism. Hence, understanding what may cause these sensory distractions will help to create a less stressful environment for an interview to take place. For example, the noise of a clock in an interview room may be distracting or cause pain for someone

hypersensitive to noise so consider moving objects out of the interview room that will cause distractions. When there are sensitivities, a holding cell or an interview room accompanied by an officer maybe more appropriate than placing a suspect with autism in a police cell alone. Although some guidance for first responders recommends attempting to move a person in the midst of a meltdown, this should not be attempted; the person can be moved to a quiet area after the meltdown has subsided.

Debbaudt (2002) highlights susceptibility in autistic people during interviews; in particular, when leading questions are asked. As a result of the susceptibility of some autistic people, they may feel that they do not need legal advice and confess to an offence that they did not commit. This is especially true if the questions were not responded to correctly due to misinterpretation. It is good practice to summarize from time to time during an interview to check understanding. If the person is quiet or confused, consider asking them to write their responses down. Allow them extra time to process information. Additionally, direct support from another person, either a family member or an appropriate adult should be considered a reasonable adjustment. An autistic person may also agree to receiving a police caution for a crime they have not committed due to anxiety of going to court and being cross-examined. It is also paramount that the person understands that accepting a police caution results in a criminal record and will affect any criminal conviction checks in the future. It is also noteworthy that in the UK, you can only appeal against your conviction, sentence, or both at a magistrates' court if you pleaded not guilty at your trial (<https://www.gov.uk/appeal-against-sentence-conviction/magistrates-court-verdict>). Therefore, a custody officer's risk assessment for an autistic person should include assigning an appropriate adult to ensure procedures are followed and understood by the detainee. An appropriate adult should be additional to legal representation and should be present during the interview. However, it is only when vulnerabilities are suspected or declared that such provision will be arranged emphasizing the importance of disclosure when in police

custody. Officers should consider taking statements from an autistic victim of a crime in surroundings familiar to them. Explain what being a witness entails and offer support if a case goes to trial.

We have explained that individuals with autism will often face higher levels of anxiety and stress than their PNT peers. Steps should be taken, as far as possible, to reduce their anxiety and stress; this will be of benefit to first responders as well as to the autistic individuals they interact with. We have set out various steps that can be taken in a variety of situations to achieve this. However, the most important action an organization can take is to train its officers (and those staff who come into contact with the public) to have an understanding of neurodiverse conditions since knowledge enhances interaction.

Future operational first responder practice *must* involve adequate training of officers and staff if interactions between first responders and persons with autism are to improve. Hence we conclude this entry with some comments on existing autism awareness training and a set of recommendations. In the United Kingdom, there have been only two studies of autism training provision by first responders – the police service in both cases – by Artingstall (2007) and Chown (2010). However, we have analyzed responses from 34 of the 43 UK police forces to a questionnaire submitted as Freedom of Information Act requests in July 2016, including a question asking for details of autism awareness training. Our data shows that there is no consistency in training provision for autism across the police service in the UK. Only 16 of the 34 respondents provide, or had provided, some form of autism training. The training provided varies greatly and may only be a PowerPoint presentation on a force website, online learning, or a 90 minute in-person session. Only five forces had involved their local autism organization in developing their training. Another force had provided four separate autism courses – each of a full day – in which they had trained almost 1200 officers and staff although almost all this training had been undertaken 4 years ago or more. In the USA, even in a situation where training is mandated by the state legislature

(New Jersey in this case), and the training is delivered on a “minimalist” online basis, a “survey indicated that a significant percentage of emergency service personnel have not completed the state mandated training” (Kelly and Hassett-Walker 2015, p. 9).

The following recommendations are made regarding future first responder autism awareness training (Chown 2010; Debbaudt 2002; Kelly and Hassett-Walker 2015):

1. While online training may have its place, in-person training is arguably far superior, especially where autistic individuals are involved in the delivery.
2. Individuals with experience of first response situations in a professional capacity *and* of autism bring a personal bond and validity to autism training. Officers and staff in first responder organizations with an immediate family relationship with a person with autism represent a potential training resource for their organizations.
3. Studies suggest that lengthier and more diverse approaches to training are often desired and covering all neurodiverse conditions rather than “just” autism.
4. Training should also be conducted jointly between the police, fire, and ambulance services, including discussion groups and role play scenarios, so that each service can contribute their own perspective and learn from the others.

First Words Project

Moira Lewis

Speech-Language Pathologist, Marcus Autism Center Children's Healthcare of Atlanta, Atlanta, GA, USA

Definition

The First Words Project is a clinical and research program, staffed by speech pathologists, researchers, and interdisciplinary consultants, aiming to investigate developmental communication disorders while providing services for young children with communication delays and their families.

An overarching goal of the First Words Project is to emphasize the importance of early screening and diagnostic methods to detect social-communication delays and disabilities in young children and to provide assessment and intervention to children and families of toddlers with delayed development who otherwise may have not had access to knowledge of the need for services.

Historical Background

Led by Amy Wetherby, Ph.D., The First Words Project conducts longitudinal research in the Autism Institute in the College of Medicine at Florida State University. The goals of the project are to identify early red flags of autism spectrum disorders and other developmental disorders in children under 2 years of age, to develop and improve early screening tools and early detection of communication disorders, and to provide training and support to families of children with ASD and other developmental disorders affecting communication.

A number of early intervention screening and assessment recommendations have been developed based on the research and work with children and families since the beginning of the First Words Project, including the use of the Communication and Symbolic Behavior Scales (Wetherby & Prizant, 2001) to identify children 6–24 months of age at risk for developmental disabilities, including autism.

The First Words evaluation model follows two-step process designed to involve participating families, thereby reducing the need for clinicians and in-home providers. The goal here is twofold, providing parents and caregivers with training and resources for developing communication and social skills in the home and reducing costs surrounding early intervention home services.

Current Knowledge

First Words Project receives national and private funding to evaluate the communication development of children from 6 to 24 months of age. For children who are delayed in communication, intervention services are offered at no cost to families or service providers, based on availability of grant funds.

Future Directions

First Words is also developing educational materials and assessment tools for training of

healthcare and childcare providers to improve early detection of communication problems in young children.

The First Words Project continues efforts to disseminate research, clinical tools, and information to all those involved in serving children with developmental disabilities and autism, including parents and caregivers. Online educational tools such as the *ASD Video Glossary*, an innovative web-based video application, are available to help parents and professionals learn more about the early red flags of autism spectrum disorders.

This ASD Video Glossary is available free of charge through the First Words Project website as well as the Autism Speaks website. The ASD Video Glossary contains over 100 video clips. Each video highlights diagnostic areas important to assess and consider when diagnosing ASD and/or differentiating ASD from other common childhood developmental delays. Each section of clips contains both child examples and short tutorials to help viewers detect subtle differences between typical and delayed development in young children and to spot the early red flags for ASD. As per the First Words Project website, all of the children featured in the *ASD Video Glossary* as having red flags for ASD are, in fact, diagnosed with ASD.

Fixed Interval

► Fixed Ratio

Fixed Ratio

Mary Jane Weiss and Samantha Russo

Institute for Behavioral Studies, Endicott College,
Beverly, MA, USA

Synonyms

[Fixed interval](#)

Definition

Fixed ratio is a schedule of reinforcement. In this schedule, reinforcement is delivered after the completion of a number of responses. The required number of responses remains constant. The schedule is denoted as FR-#, with the number specifying the number of responses that must be produced to attain reinforcement. In an FR-3 schedule, 3 responses must be produced in order to obtain reinforcement. In an FR-15 schedule, 15 responses must be emitted before reinforcement is delivered. This ratio requirement (number of responses to produce reinforcement) is conceptualized as a response unit. In other words, it is the response unit (not the last response) that leads to the reinforcer (Cooper et al. 2007; Skinner 1938).

Applications of FR schedules can be found in business and in education. Some tasks are paid on an FR schedule (e.g., piecework). Students might

receive a token after the completion of ten spelling words.

FR schedules are associated with a particular pattern of responding. After the first response, there is generally little hesitation between responses and the required responses are completed. After the ratio requirement is met, reinforcement is delivered. This is followed by a postreinforcement pause, in which the participant does not respond for a period of time following reinforcement. The size of the ratio influences the length of the pause. Duration of the postreinforcement pause is greater for large ratio requirements. Shorter pauses occur with small ratio requirements. The FR schedule is visually depicted as a stepwise pattern.

FR schedules produce high rates of responding. It is associated with rapid response speed, since completion of the ratio requirement leads to reinforcement. In general, higher ratio requirements produce higher rates of responding (to gain more reinforcement). If the ratio requirements are too stringent, however, the rate of response can decrease. The maximum ratio must be individually determined and continually monitored. The determination of the maximal value is influenced by motivating operations, the individual's reinforcement history, and the quality of the reinforcer.

Synonyms

[Derailment](#); [Loose associations](#); [Tangentially](#)

Definition

Flight of ideas is a formal thought disorder. It refers to the expression of rapidly shifting thoughts in an individual. Thoughts are expressed through language. In individuals with “flight of ideas,” thoughts are expressed in a highly associative manner. These associations may be linked to cue in the surrounding environment, elicited by associations stemming from the topic or merely by words. The individual’s speech becomes incomprehensible, because he does not tune into the listener’s needs by providing the listener with information that prepares him for changes of topic of conversation, thus making these better understandable.

Flight of ideas may occur in the course of a manic episode, during a psychosis, but is not uncommon in individuals with an autistic disorder of multiple complex developmental disorder. In the latter individuals, the question is raised whether this is really a thought disorder or a communicative deviance more related to expressive language disorder in these individuals. Others (Raymond Lake 2008) consider thought disorder as an expression of mood disorder.

Floor Effect

Hillary Hurst
Department of Psychology, University of
Massachusetts Boston, Boston, MA, USA

Definition

The floor effect is a statistical phenomenon in which most data points fall in the very low range of possible values (“bottom out” on the “floor” of the measure). The floor effect is often seen in assessment when a test is too challenging for a given target population. In turn, many subjects obtain scores that are clustered together at the bottom of a measure, with very few extending

across the possible range of scores. This results in a skewed distribution with very limited variability. Floor effects greatly limit the clinical utility of measures. For example, if there are floor effects on a measure prior to and following an intervention designed for individuals with ASD, it will not be possible to observe any actual benefits that might have occurred for participants.

Floor Time/Circle of Communication

Laura Bonazinga Bouyea
Vermont Speech Language Pathology, University
of Vermont, South Burlington, VT, USA

Definition

Floortime is one component of the Developmental, Individual-Difference, Relationship-based (DIR[®]) approach for engaging children with autism spectrum and related socioemotional disorders. The DIR[®] model provides an interdisciplinary approach for practitioners, educators, and families to comprehensively assess and provide intervention according to the unique developmental profile of the child. Floortime focuses on creating opportunities of connection between the care-provider and student, fostering learning through emotionally engaging and meaningful interactions while encouraging mastery of six

foundational stages of social, emotional, and intellectual development (Greenspan and Wieder 2006). Previous implementation suggested the ideal targeted population to be in the early toddler years; however, more recently the authors have expanded the target population to include older children and adolescents who have developmental differences. The initial goal of Floortime is to discover individual differences in sensory processing, language, motor, visual, and intellectual capacities, as well as identify the child's view of the world by attending to the child's interests, sensory modulation and processing, motor planning, and symbolic formulation and use. The practitioner then enters into the child's world by imitating or following the child's lead, attempting to draw the child into a shared interaction (Davis et al. 2014). Once an initial affective interaction is established, the clinician encourages a response, creating a *circle of communication* marked by an increase in intentional or purposeful two-way communication.

When the foundational skills of opening (initiating) and closing (responding to) circles of communication have been established, more complex areas of social, emotional, and intellectual capacities are fostered by creating small obstacles or variations during Floortime (Greenspan and Wieder 1997). The DIR[®] approach, of which Floortime is a part, emphasizes individualized early intervention to treat the developmental differences often observed in autism (Landa et al. 2007) in consideration of the child's unique presentation of social, cognitive, and processing deficits.

Historical Background

Stanley I. Greenspan first developed and presented the DIR[®]/Floortime approach for treating children with developmental and emotional disorders in 1992. Greenspan and colleagues, including, Serena Wieder, drew from interventions across disciplines to hone and perfect a comprehensive and child-led approach for intervening with nonprogressive developmental disorders, such as autism spectrum disorders (ASD), from a

functional developmental framework instead of treating individual symptoms (Greenspan and Wieder 1999).

The development of the DIR[®]/Floortime model has as its foundation the most influential research in the field of developmental psychology (ICDL 2000) dating back to the early work of Jean Piaget (1896–1980) and Lev Vygotsky (1896–1934). Piaget hypothesized that there was a typical progression through human development whereby babies construct or build on innate “schemas” about the world as they progress through four stages of cognitive development. This theory, which became known as the constructivist view of learning, suggested that children have an innate or intrinsic motivation to interact with others and play, gathering and constructing knowledge about the world, through which they form the foundation for understanding abstract and symbolic representations of the world (Huitt and Hummel 2003; Prelock 2006). The significance of play in learning and development was also an idea shared by Vygotsky; however, he suggested a more sociocultural view of cognitive development (Prelock 2006), as he posited that it was through the continued interaction with others that developmental changes occurred in individuals (Cole and Scribner 1978).

In 2004, Greenspan and Shanker suggested that while play was important for general development, emotions and, more specifically, affective signaling between communicative partners during play directly allowed for individuals to develop their “first idea,” a mental construct or representation of something intangible. They hypothesized that through the development of emotional understanding and reciprocal signaling, play and social interaction lead to symbolic reasoning and higher-order cognition. Drawing from the literature and research on the core deficits defining ASD, they developed a model of functional developmental capacities that when absent or reduced led to decreased formation of the foundations for relating, communicating, and thinking.

Historically, treatment approaches for ASD follow two models for intervention: behavioral approaches for reducing maladaptive or inefficient behaviors and cognitive approaches for

training individual skills according to the absence or presence of expected abilities at a given age (Greenspan and Wieder 2006). In the development of the DIR[®]/Floortime model, the authors defined the core goal areas based on relevant areas of developmental functioning that may or may not have been impaired in a given disorder. They reasoned that the very foundation of a comprehensive treatment program was to build upon a core set of skills that are requisite for the development of more broad and higher-cognitive skills. Using the authors’ experience in emotional and social development, and their focus on treating a multifaceted neurodevelopmental disorder with interventions across several disciplines, they suggested the DIR[®] model, which included all relevant and critical areas of development, including systems responsible for emotional, social, language, motor planning, and sensory processing and modulation.

Rationale or Underlying Theory

The development and expansion of play skills has gained recognition as serving an integral role in the acquisition of cognition, language, emotional intelligence, and social skills in children (National Research Council [NRC] 2001; Prelock 2006). Further, it has been suggested that a connection with an adult, during play and social routines, scaffolds and informs the child’s ongoing development of meaning, beliefs, and values for the social context, thereby influencing the child’s ability to expand his/her knowledge through experiences with objects, actions, and events (Greenspan and Shanker 2004; Greenspan and Wieder 2006; NRC 2001; Prelock 2006). As intervention techniques begin to broaden and include more intensive and early intervention programs, some suggest a developmental and relationship-based approach may be more effective for treating children with ASD. *Development*, *Individual Differences*, and *Relationships* are three integral aspects of the Floortime approach, which purport to form a strong foundation from which several strategies can be used to create attuned relationships, which thereby foster continued brain

development. *Development* refers specifically to a symbolic ladder, corresponding to a typical developmental trajectory of social emotional capacities, which successively lead to the development of intimacy, mutuality, intentionality, empathy, creativity and resilience. *Individual Differences* reflect the importance of the acknowledgment, examination, and integration of differences across how individuals functionally engage in sensory registration, modulation, and interpretation; and language and motor processing; as well as interpret related concepts. *Relationships* are defined as the development of warm, flexible, sensitive, and open adult-child connections leading to finely attuned relationships, which provide the firm foundation to support neural integration, socio-emotional, and sociocognitive growth (Davis et al. 2014).

Limited ability to relate and emotionally connect within the social context is inherent in the core deficits often observed in ASD and related sociocommunicative disorders. This limitation, coupled with a reduced or lack of initiation and/or attention toward others, restricts the child's ability to form ideas and expand their knowledge of reciprocal and symbolic play (Greenspan and Wieder 2006; Mundy et al. 1990; Prelock 2006). Greenspan and Shanker (2004) refer to the early development of a "first idea" as a primitive construct that leads to the integration of symbolic, linguistic, and intellectual knowledge. This, in turn, allows for the child to appreciate the ever-changing social context and navigate the dynamics of play leading to increased interpersonal communication.

In 1997, Greenspan and Wieder presented a paradigm of Functional Developmental Levels (FDLs) that reflected expected capacities in relating, emotional understanding, and symbolic representation throughout six stages of typical development. They posited that typical development progresses through successive mastery of each stage and is essential for normal development of emotional reasoning, a matured sense of self as well as higher-level cognitive development. Later these stages were expanded to include some higher-level aspects of emotional understanding, affective reasoning, and cognition, and

are now referred to as Functional Emotional Developmental Capacities (FEDCs) (Greenspan and Wieder 2006). Consequently, for the purpose of clarity, they will be referred to as FEDCs and are described in more detail below.

Stage one of the FEDCs is the capacity for *mutual or shared attention* or the ability to regulate attention and behavior while monitoring and processing sensory information from the environment and one's own body. Self-regulation is one component of this stage whereby a child learns the association between a physical state and an emotion. Another component is the emergence of joint attention, typically occurring between 6 and 9 months of age, although children begin processing sensory information shortly after birth. The capacity for joint attention is also viewed as a prerequisite skill for later language and communicative development (Mundy et al. 1990). Successful joint attention between caregiver and child begins to foster the child's knowledge for discriminating pleasurable from unpleasurable experiences (Greenspan and Wieder 2006). It is through initial sensory processing paired with increased attention to others during mutually shared experiences that a child's emotional understanding begins to deepen.

Stage two typically emerges between 2 and 5 months of age and is marked by *engagement and relating with others*. As a child's ability to engage in emotional interactions increases, so does the ability to discriminate between an interaction with another social being and an inanimate object. Through this discrimination, the child recognizes patterns about his/her world and demonstrates an emerging ability to assign meaning to various acts of communication and symbolic representation. During this stage, a child's genuine desire for engaging and relating begins to emerge, without signs of distress or withdrawal, affording more opportunities for increased reciprocal communication.

The third stage, *intentionality and two-way communication*, is marked by the child beginning to interpret emotions as "signals" of communication. By 6 months of age, caregivers and babies begin to engage in intentional or purposeful communication where caregivers read and respond to

children's emotions and, in turn, require them to read and respond to theirs. The result is a back-and-forth flow of emotional signaling, which is referred to as a "circle of communication." As the child approaches 8 months of age, circles of communication are mastered and become longer and more frequent, expanding the child's understanding of interactions as following a causal and logical pattern, mimicking the turn-taking pattern of more complex and later developing skills such as in maintaining a conversation.

Between 9 and 18 months of age, children begin to master the fourth stage of the FEDCs, *social problem solving, mood regulation, and formation of a sense of self*. In this stage, two-way reciprocal communication is used to solve problems and achieve a desired goal (e.g., pointing to direct others' attention or to obtain a desired object). Developing emotional maturity at this stage allows for an increase in *shared social problem solving*, where a child considers not only his/her own thoughts and beliefs but also the thoughts and desires of another individual and engages in negotiations during play and communication. Further, the emergence of skills in *regulating mood and behavior* allows a child to rapidly recognize and adjust his/her emotional signals. It is during this stage that children begin to develop an understanding of cause and effect and become more aware of complex patterns of communication leading to an early *sense of self*. They begin to refer to themselves as "I" or "me" and others as representing "you." This sense of self and others leads to early empathetic reasoning or a theory of mind.

By one and half years of age, the child's development progresses into the fifth stage of FEDCs, *creating symbols and using words and ideas*. Through joint attention and complex emotional signaling the child learns to separate perceptions from actions and begins to pair mental constructs, or images, with a linguistic or gestural symbol. Communication becomes meaningful and pretend play becomes more imaginative (e.g., a block as a car or a pan as a hat). A better understanding of the function of words and symbols emerges, and a child learns that words and actions communicate ideas, convey mental and physical states, and signal intent.

As a child progresses through the second year of life, at approximately two and a half years of age, he/she enters into the sixth stage of FEDCs, *emotional thinking, logic, and a sense of reality*. The child begins to connect symbols and ideas in a logical manner. The ability to link an internal to an external idea emerges as well as a child's sense of events across time. As the child's logical thinking expands, higher-cognitive skills emerge such as inventing characters or games and following the rules of another's game.

Assessment of the child's functional capacity at each of the aforementioned stages forms the core of the DIR[®] model and further informs treatment at each stage through child-centered, interactive, and guided Floortime sessions. At the heart of the intervention is the premise that through maturing emotional development, a child learns to construct his/her knowledge of the world, learning to construe multiple representations or symbols for events, eventually leading to reciprocal social competence through an understanding of the self and others (Greenspan and Wieder 2006).

Goals and Objectives

Two common goals are at the heart of the Floortime approach: (1) following the child's lead, identifying that child's unique processing style and/or interests in the environment, and (2) bringing the child into a shared world, using two-way intentional and reciprocal interactions (Greenspan and Wieder 2006). In addition, three cornerstones have been identified as essential to participation in the program. First, relationships are formed through emotional and meaningful interactions and are the context for learning that leads to the development of language, cognition, and social skills. Second, motor and sensory processing capacities are varied in children, and these variations affect the emotional processing that goes along with interpreting and modulating sensory information. In essence, children vary in the way they process information, thereby making their availability for learning and relating individually unique. Finally, progress across all developmental areas should be viewed as interrelated.

Considering these three cornerstones the main goal of the Floortime approach is to increase a child's capacity for thinking of themselves as intentional and interactive individuals as they progress through mastery of the six FEDCs described above (Greenspan and Wieder 2006). The initial step is to administer a comprehensive interdisciplinary assessment of the child's developmental capacities within the context of his/her unique sensory processing profile, the dynamic of his/her family relationships, as well as his/her interactive patterns (Greenspan and Wieder 1999). A functional developmental profile is derived from clinical observations of interactions with both clinicians and parents, chart reviews, interviews with other care providers, assessments across disciplines (speech-language pathology, occupational therapy, physical therapy, etc.), a developmental history, a review of current programs, as well as a biomedical evaluation.

Following the generation of a functional developmental profile, a comprehensive DIR[®] intervention program is developed with goals that are individualized to the unique profile of the child while considering functioning across the six areas of functional emotional development. The foundational goal is meeting the child's need for a connection with others by providing stable and secure relationships with providers. Upon the foundation of ongoing emotional interactions with consistent care providers, individualized therapeutic goals can be designed to specifically address the child's functional developmental level, his/her individual differences in sensory processing, motor planning, and sequencing, as well as specific skills in the areas of speech and language and general education. Lastly, the authors highlight the importance of continual team and family consultation as well as ongoing assessment of core deficits as well as the functional developmental capacities, which further informs the progression and predicted outcome of an individualized DIR[®] program.

Treatment Participants

The DIR[®]/Floortime approach was designed for children and adolescents with developmental

differences, specifically, socioemotional deficits such as those often observed in ASD. It is appropriate for individuals who are verbal or nonverbal and with a diagnosis of ASD (Ingersoll et al. 2005) or related sociocommunicative disorders. While there are no prerequisite skills necessary to begin a DIR[®] program, researchers have found that individuals who benefit most from this treatment tend to present as having a specific profile, quite possibly allowing them to be more capable of learning to relate and interact with intentionality and symbolically. The children who have a more positive prognosis with the DIR[®] approach are those that have demonstrated some capacity for joint attention and an emerging ability for using gestures in an affective interaction. In addition, they typically demonstrate some form of functional language use or some degree of pretend play (Greenspan and Wieder 1997). Lastly, while this approach has typically been implemented with toddlers, recognizing early intervention leads to better outcomes for children who are identified early as having developmental delay (Landa et al. 2007), it can also be used with older adolescents with autism who have some functional capacity at each of the six FEDCs, but continue to struggle with higher-level thinking. For older children, this model is typically implemented within a school program or in community environments that purport to foster and facilitate social interaction (Greenspan and Wieder 2006).

Treatment Procedures

A comprehensive DIR[®] program typically involves a home-based program, an educational setting-based program, as well as the addition of specialized therapies such as speech and language, occupational, physical, and/or certain biomedical therapies, depending on the needs of the child (Greenspan and Wieder 2006). The mean age for entry into a DIR[®] program is typically 36 months, ideally beginning as early as 22 months (NRC 2001) or immediately following identification of key strengths and challenges in affective reasoning, sensory modulation and

processing, symbol formulation, and motor planning through a comprehensive, interdisciplinary assessment. However, this approach is also used for older children and adolescents who demonstrate developmental differences, particularly in the area of social emotional relatedness. Floortime training and mentoring can be implemented in the home or clinical setting by a trained professional in the discipline of speech-language pathology, psychology, or a person with training and expertise in the application of the Floortime approach. Eventually parents are trained to implement these techniques as well. Duration of intervention ranges from 10 to 25 h per week (NRC 2001). One pilot study has suggested that implementation of the approach by parents for as little as 15 h a week can potentially produce both positive outcomes and remain cost-effective for families (Solomon et al. 2007). However, one limitation noted that, for children whose parents spent less than the prescribed time implementing the program, there was less progress in the functional developmental level observed, supporting the importance of duration and frequency of treatment, as suggested by the NRC (2001).

The most common technique applied in the DIR[®] model is Floortime interactions, which occur both at home between clinician and child as well as between parent and child. These sessions are designed to be approximately 20 minutes per session and are ideally spontaneously interspersed throughout the day for a frequency of at least eight sessions. Once the child has mastered the initial functional developmental capacities required for interaction (e.g., joint or shared attention and can complete multiple circles of communication), peer play sessions can be introduced to facilitate shared problem solving, play negotiation, and the exchange of symbols, gestures, or words. Additional structured and semi-structured sessions are implemented to address specific skills in the areas of motor, sensory and spatial skills, balance and coordination, and visuospatial functioning.

Several strategies specific to DIR Floortime have been identified as techniques for promoting therapeutic relationships which in turn foster continued functional social emotional and

sociocognitive development. These are outlined in *Floortime Strategies to Promote Development in Children and Teens* (Davis et al. 2014). The highlighted strategies include, but are not limited to, intervention techniques to support: the attunement of relationships, securing connections, responding and expanding to reciprocal bids for communication, fostering pretend and symbolic play, and challenging and reflecting upon interactions to foster more complex thinking.

There is a clear interdisciplinary and collaborative effort inherent in the DIR[®] approach, allowing a plan to be individualized to each child's unique functional developmental profile. Specialized therapeutic services, such as speech-language pathology, occupational, and/or physical therapy, are implemented, as needed, in addition to Floortime sessions. Several components of the DIR[®] model, however, are implemented or facilitated by parents. The affect-based curriculum is one such component, which is specifically designed to include highly motivating semi-structured, structured, and spontaneous activities that are based on a common goal of sharing affect and attention while simultaneously focusing on the foundations of language, such as phonology, syntax, grammar, and semantics (Greenspan and Wieder 2006).

Efficacy Information

Efficacy of the DIR[®] model has been measured using the *Functional Emotional Assessment Scale* (FEAS) for the child and the caregiver, by clinical measurement of the Functional Emotional Development Level (FEDL), or the child's functioning according to the six developmental levels suggested by Greenspan and Wieder (1997) as well as in overall presentation and severity of symptoms in autism. In a retrospective chart review of 200 cases conducted by Greenspan and Wieder (1997), it was reported that children's progress could be organized into three outcome areas of the intervention. Fifty-eight percent of the cases were interpreted as having *good to outstanding* outcomes, 25% of the cases had *medium outcomes*, and 17% demonstrated *ongoing*

difficulties. The conclusions of this review suggest that a small subgroup made progress in learning to relate to others, communicate, think creatively and abstractly, and showed an increase in emotional understanding and empathy, while other cases, measured as having more severe symptoms, continued to have difficulties despite intervention. Limitations noted in this chart review included variability in the assessment procedures used for the 200 children, the limitations associated with a case study design, and a small sample size, therefore suggesting that these results could not be definitively generalized to the greater population with ASD.

Later, a 10–15-year follow-up of a subgroup of children with ASD who received the DIR[®] intervention program was conducted by the same authors. This study revisited 16 in the subgroup of children who were reported to have *good to outstanding* outcomes from the earlier chart review of 200 cases (Greenspan and Wieder 1997). Conclusions from the follow-up study indicated that most individuals from that subgroup maintained the progress in the areas of social relatedness, creative thinking, and empathy, suggesting that early implementation of the DIR[®] approach may have effects later into adolescence. Limitations included questions about the generalizability to the larger population of children with ASD, the sample size, and extraneous factors that could not be controlled for, such as other interventions implemented across the years (Wieder and Greenspan 2005).

In 2005, Ingersoll and colleagues examined the effects of the Developmental Social-Pragmatic model (DSP) on the use of spontaneous functional communication of three children with ASD between the ages of 2 and 3 years of age. Through a single subject-multiple baseline design, trained therapists implemented a DSP model of treatment, which included the DIR[®]/Floortime approach, Hanen program, SCERTS model, and responsive teaching approaches. The children received treatment twice weekly for 10 weeks, followed by a 1-month follow-up to assess generalization. The authors found that two of the three children demonstrated gains in spontaneous language use after treatment began that was maintained and

generalized across new treatment settings. The third child exhibited gains in spontaneous communication; however, he also demonstrated an increase in his baseline, thereby confounding the interpretation that his gains could be solely attributed to the DSP intervention. The conclusions of this study speak to the strength in the application of this research model and support evidence for DSP models implemented by specialists in the field of speech and language as well as the use of spontaneous functional communication as a preferred outcome measure. In addition, progress in spontaneous communication following the use of the DSP model for both verbal and nonverbal children with ASD was found. Limitations included the absence of a follow-up session for one child, a failure to explore generalization to more naturalistic settings, as well as an inability to control for the therapists being the sole providers of the DSP approach throughout the duration of treatment.

Further support for the DIR[®]/Floortime approach was found by Solomon et al. (2007) who conducted a pilot study that focused on training and consultation for parents implementing the Floortime approach across an 8- to 12-month program. Their study found significant gains for 45.5% of the children enrolled as indicated by an increase in their overall FEAS score. In addition, no significant changes in the caregivers FEAS scores were observed, suggesting that parent's participation was appropriate for implementing the relationship-focused intervention. Mahoney and Perales (2005) also reported that the parent implementation of the relationship-based intervention model for children with pervasive developmental disorder (PDD) was effective, encouraging the caregivers to provide more responsive interactions with their child, which in turn led to more than two thirds of the children demonstrating an increase in their targeted developmental behaviors. The research published on the DIR[®] model suggests that parent education, training, and provider roles are factors that positively influence the outcome of changing pivotal behaviors in children treated with this approach (Mahoney and Perales 2005; Solomon et al. 2007). Another factor affecting the outcome of

treatment is the amount of time spent with the child implementing Floortime (NRC 2001; Solomon et al. 2007).

By 2010 there was some research supporting positive outcomes for a subgroup of children participating in early DIR[®] intervention, with most research including case studies and chart reviews, which indicated the need for further and more stringent research models. Based on the National Autism Center's first phase of the National Standards Report (2009), developmental and relationship-based approaches were considered to have emerging evidence, further highlighting the need for more research examining the outcomes of such programs for addressing the individuals with ASD. In 2015, Phase Two of the National Standards Report (2015) was published providing further confirmation that the DIR/Floortime model has emerging evidence, suggesting that approximately seven studies indicate beneficial intervention effects for a set of interventions categorized as developmental and relationship-based approaches; however, more rigorous research is still needed to draw firm conclusions regarding the overall efficacy of this model.

In 2011, a pilot randomized controlled trial, conducted by Pajareya and Kopmaneejumrulers, focused on parent training and confirmed that the addition of home-based, parent-led Floortime sessions at an average of 15.2 h per week across 3 months led to clinically significant gains in social emotional functioning. Additionally, since 2011 one study has also demonstrated the effectiveness of training the caregiver in the implementation of DIR/Floortime strategies. This study examined the efficacy of implementation of the home-based Play and Language for Autistic Youngsters (PLAY) Project and demonstrated that there were significant gains in functional development reflected in the diagnostic categories on the Autism Diagnostic Observation Schedule (ADOS) as well as large treatment effects for parent-child interactional behaviors (Solomon et al. 2014). One additional study identified significant gains in discrete social skills, including: turn taking; reciprocal, or two-way,

communication; understanding cause and effect; and emotional thinking following intensive early intervention using the Floortime approach (Lal and Chhabria 2013).

Outcome Measurement

The DIR[®] model uses two outcome measures, the *Functional Emotional Assessment Scale* (FEAS) and the *Greenspan Social Emotional Growth Chart* (SEGC), to assess baseline levels at the initial evaluation, measure progress at follow-up sessions, and establish outcomes of the therapy (NRC 2001). The initial evaluation of a child should include developing a profile of that child's individual functioning when compared to the six stages of emotional development. Visual-spatial and motor planning should also be assessed to determine the child's ability to process information (Greenspan and Wieder 2006).

The FEAS is a criterion-referenced tool for measuring functional emotional capacities in children ages 7 months through 4 years of age. More specifically, the FEAS systematically assesses the child's ability to negotiate play activities in relation to people or objects, to self-regulate mood and attention, to form attachments with the caregiver, to use emotional and communicative reciprocity, and to represent emotions, ideas, and emotional thinking within the context of play interactions from videotaped samples. A caregivers' capacity to support development in the aforementioned areas of emotional development is also assessed (Greenspan and DeGangi 2001). In addition to the two measures noted above, continued assessment of the child's functioning in each of the stages of FEDCs informs the direction of treatment as well as progress across developmental areas (Greenspan and Wieder 2006).

Qualifications of Treatment Providers

The DIR[®]/Floortime model is considered to be a comprehensive and individualized approach

that can be developed and adjusted according to the child's individual differences, family dynamics, and level of development. The development of the program requires participation of several disciplines: speech-language pathologists, occupational or physical therapists, early educators and/or special educators, and a therapist trained in intensive Floortime work (Greenspan 1992a as cited in Greenspan and Wieder 1997).

Although multiple care providers with expertise in several disciplines are required for the development and implementation of a comprehensive DIR[®] program, parents play an essential role as providers of spontaneous Floortime sessions throughout the day (Greenspan and Wieder 2006). Additionally, while several specialists with relevant training in his/her area of expertise may cooperate in implementing the Floortime approach, the application of a comprehensive DIR[®] approach should be managed and overseen by a specialist from a relevant discipline, who has training in applying DIR[®] theory. The Interdisciplinary Council on Developmental and Learning Disorders (ICDL) provides a few training opportunities for licensed professionals from several disciplines, such as speech-language pathology, occupational and physical therapy, as well as social work, to name a few. Among the training opportunities offered, there is a DIR[®] introductory level course, a DIR[®] beginning course, as well as an intensive DIR[®] certification program. Information regarding further information and training opportunities on the DIR[®] model can be found at www.icdl.com.

Fluency and Fluency Disorders

Diane R. Paul

Clinical Issues in Speech-Language Pathology,
American Speech-Language-Hearing
Association, Rockville, MD, USA

Synonyms

Cluttering; Disfluency; Dysfluency; Nonfluency; Stammering; Stuttering

Definition

Fluency is the aspect of speech production that refers to continuity, smoothness, rate, and effort (American Speech-Language-Hearing Association [ASHA] [n.d.](#)). *Stuttering* is the most common fluency disorder. Stuttering is an interruption in the forward flow of speech and is characterized by repetitions (sounds, syllables, words, phrases), sound prolongations, blocks, interjections, and revisions, which may affect the rate and rhythm of speech. These disfluencies may be accompanied by physical tension, negative reactions, secondary behaviors, and avoidance of sounds, words, or speaking situations (ASHA [1993](#); Yaruss [2007](#)).

Incidence and Prevalence

The lifetime incidence of stuttering is approximately 5% or higher (Mansson [2000](#); Yairi and Ambrose [2013](#)). Among children, the incidence reaches a rate of 8.5% by 3 years and 11% by 4 years (Reilly et al. [2013](#)). Stuttering is more common among males than females. Among elementary school-age children, it is estimated that boys are three to four times more likely to stutter than girls (Craig et al. [2002](#)). The estimated prevalence rate for stuttering across ages is 0.72% (Craig et al. [2002](#)).

Fludac

► Prozac™ (Fluoxetine)

Types of Disfluencies

All speakers have disfluencies, which may include hesitations for language formulation including silent pauses as well as insertion of word fillers (e.g., “The book is *like* new”) and nonword fillers (sometimes called *interjections*, e.g., “My friend is *uh* driving”); other examples also may include whole-word repetitions (e.g., “Go-go get that bottle”) and phrase repetitions or revisions (e.g., “*Don’t tell me-* don’t tell me again”). These may be considered “more typical,” nonstuttering disfluencies when there are a small number.

Less typical, more stuttering-like disfluencies include *part-word* or *sound/syllable repetitions* (e.g., “Give me the *p-p-p* pencil”), *prolongations* (e.g., “*Sssssss*stay here with me”), and *blocks* (i.e., silent fixations or inability to initiate sounds). In addition, stuttering-like disfluencies are usually accompanied by decidedly greater than average duration, effort, tension, or struggle than are typical disfluencies.

Developmental Progression

Stuttering most often begins during childhood. Some young children go through a period of excessive disfluency. However, they go on to display typical fluency skills as their language abilities develop. A large majority of early stuttering remits without clinical intervention, although recovery estimates vary greatly from 6.3% (Reilly et al. 2013) to 89% (Yairi and Ambrose 1999).

Impact of Stuttering

Stuttering can greatly interfere with school, work, or social interactions. Children and adults who stutter may report fear or anxiety about speaking and frustration or embarrassment with the time and effort required to speak. Despite popular beliefs, emotional problems or emotional trauma do not cause stuttering. However, dealing with stuttering can result in significant emotional reactions and avoidance behavior. Stuttering is often more

severe when there is increased pressure to communicate (e.g., giving a presentation, interviewing for a job).

Causes

The cause of stuttering is presently unknown but may reflect subtle underlying differences in brain structure and function, particularly when an individual is processing and producing language. Stuttering may have a genetic component and the risk of stuttering is elevated in families having other members with persistent stuttering. Stuttering can also occur following neurological trauma (e.g., brain injury) and following psychological trauma (e.g., posttraumatic stress disorder).

Cooccurrence

Stuttering can cooccur with other disorders. For example, although there is little systematic evidence describing disfluency in autism spectrum disorder (ASD), increasing numbers of case reports indicate atypical, stuttering-like behaviors that are additionally distinguished by unusual features, such as repetition of final segments of words (Paul et al. 2005; Shriberg et al. 2001; Sisskin and Wasilus 2014). Children who stutter may show expressive language problems because of a tendency to avoid speaking. Less talking and reduced linguistic complexity may result (Silverman and Bernstein Ratner 2002).

Terminology

The term disfluency (sometimes spelled dysfluency) often is used synonymously with stuttering. However, the term disfluency refers to typical and atypical breaks in the forward flow of speech, while stuttering refers to a fluency disorder, characterized by a high number of less typical disfluencies and usually a greater effort to speak. *Stammering* is synonymous with *stuttering* and is the common term for the disorder in Great Britain. In North

America, the term *stammering* is rarely used. *Secondary behaviors* are also known as *accessory behaviors*, *secondary mannerisms*, *secondaries*, *concomitant behaviors*, or *extraneous behaviors*. For example, a person may tap his foot or nod her head while talking in a misplaced effort to speak fluently. Secondary behaviors usually start coincidentally and then become incorporated when the person notices an improvement in fluency. If a behavior appears to help, it may persist, even though it loses its effectiveness.

Cluttering

Cluttering is another fluency disorder. Cluttering is characterized by a rapid and/or irregular speech rate, and excessive disfluencies, which are usually of the more typical type (revisions and overuse of filler words, such as “um”). The speech of a person who clutters often contains pauses in unusual places and unusual prosody (St. Louis and Schulte 2011). Other symptoms may include language or phonological errors. Cluttering has been documented in children with autism (Scaler Scott 2011).

Speech-Language Pathologists

Speech-language pathologists (SLPs) are the professionals who perform fluency assessments and intervention individually or in groups. SLPs also serve as members of collaborative teams that may include the individual, family/caregivers, educators, and other relevant persons.

Definition

Fluid intelligence (abbreviated Gf) is the ability to reason quickly, think abstractly, and problem-solve, independent of acquired knowledge. Cattell (1971) proposed two factors underlying general intelligence: fluid and crystallized intelligence. Tests of fluid intelligence tap current reasoning ability and are considered to be more “culture-fair,” being less affected by differences in learning experience or test familiarity. Raven's Progressive Matrices, and other tasks with novel stimuli, are thought to tap fluid intelligence.

People with ASD often do well on certain tests thought to measure fluid intelligence, such as Raven's Matrices (Hayashi et al. 2008) and Block Design (Shah and Frith 1993). Interpretation of these peaks in an uneven intelligence test profile has varied: many fluid intelligence tests

tap visuospatial problem solving, which may be superior to verbal reasoning in many people with autism. Alternatively, Dawson et al. (2007) have suggested that good Raven's Matrices scores reveal the true level of intelligence in autism, underestimated by standard IQ tests. Scheuffgen et al. (2000) suggested that people with autism may have good potential processing efficiency (as seen in fluid intelligence tests), not reflected in standard IQ test performance because of failure to acquire skills and knowledge through socially mediated learning. Fluid intelligence is thought to include several processes, only some of which may be superior (relative to own profile or others') in autism; visualization and pattern recognition, for example, may be areas of skill, while ideational fluency or generativity (see ► [“Behavior Observation Scale”](#)) may not.

Indications

Fluoxetine is FDA-approved to treat major depressive disorder (MDD) in both adults and in children aged 8–18 years old, obsessive-compulsive disorder (OCD) in both adults and children aged 7–17 years old, and bulimia nervosa in adult patients. In these disorders, fluoxetine can be used both acutely and as maintenance therapy. It is approved for adults only in the acute treatment of panic disorder with and without agoraphobia. In combination with olanzapine, marketed as Symbyax, it is approved for the acute treatment of depressive episodes associated with bipolar I disorder and treatment-resistant depression in adults only (Lilly 2009).

Fluoxetine is not approved for the treatment of autism spectrum disorders (ASDs), which include the DSM-IV-TR diagnoses of autistic disorder, Asperger's disorder, and pervasive developmental disorder, not otherwise specified (PDD-NOS). The decision to use fluoxetine in the treatment of established clinical indications that may co-occur with ASDs, as mentioned above, or for commonly observed symptoms of ASDs, such as hyperactivity, inattention, irritability, aggression, repetitive behaviors, and social impairment, can be made on an individual basis by the treating practitioner.

This will be discussed in more detail in the “[Clinical Uses](#)” section.

Mechanisms of Action

Fluoxetine is a selective serotonin reuptake inhibitor (SSRI). Normally, serotonin is released from the presynaptic axon terminal to travel across the synaptic cleft and attach to the postsynaptic axon terminal. Any excess serotonin remaining in the cleft is picked up by the serotonin reuptake transporter in the presynaptic axon to be degraded and recycled. It is hypothesized that a depletion of serotonin available to act on the postsynaptic axon results in symptoms experienced in mood and anxiety disorders, like sadness, nervousness, guilt, loneliness, apathy, and avolition. Fluoxetine attaches itself to the serotonin reuptake transporter and prevents whatever serotonin remains in the cleft from being degraded. The excess serotonin is free to attach to postsynaptic receptors and exert its intended effects (Stahl 2008).

Although fluoxetine begins acting immediately to inhibit serotonin reuptake, its antidepressant and anxiolytic effects are often not experienced for up to 6–8 weeks. This is thought to be due to gradual changes fluoxetine makes on serotonin receptor sensitivity. It is believed that the decreased amounts of serotonin found in mood and anxiety disorders cause the postsynaptic axon to upregulate the number of postsynaptic axonal receptors expressed. In other words, a decreased amount of serotonin in the synaptic cleft results in an increased amount of receptors at the ready. When fluoxetine enters the picture, the level of serotonin in the cleft rises. Postsynaptic receptors recognize the serotonin increase and send messages to the axon nucleus about the changes in the synaptic cleft. The nucleus begins downregulating the amount of serotonin receptors ready to receive serotonin. These changes are gradual and are believed to take 6–8 weeks before fully completed, reflecting the amount of time before many patients begin feeling relief from their symptoms (Stahl 2008).

Fluoxetine's antagonism of the postsynaptic 5-HT_{2C} receptor results in some of its unique therapeutic effects. When serotonin attaches to

the 5-HT_{2C} receptor, it blocks the release of neurotransmitters norepinephrine and dopamine in the brain. When fluoxetine blocks the postsynaptic 5-HT_{2C} receptor, norepinephrine and dopamine are instead released and exert their effect in the prefrontal cortex. The effect is activating, often leading patients to feel more energized, less fatigued, and to have improved concentration and attention. Fluoxetine is therefore considered for patients whose constellation of symptoms includes fatigue, apathy, and avolition as opposed to nervousness, insomnia, and agitation. Other therapeutic effects from postsynaptic 5-HT_{2C} antagonism include anorexia and anti-bulimia, particularly at higher doses of fluoxetine, and relief from bipolar depression when combined with olanzapine, a second-generation antipsychotic. Of note, neither olanzapine nor fluoxetine alone is approved for the treatment of bipolar depression. However, they both antagonize the 5-HT_{2C} receptor. This combined antagonism likely boosts norepinephrine and dopamine release in the cortex and may be what drives the antidepressant effect seen in the treatment of bipolar depression. The combination of fluoxetine and olanzapine is marketed as Symbyax with a fixed-dose ratio of fluoxetine to olanzapine, although both can be prescribed separately.

Fluoxetine also weakly attaches to the norepinephrine transporter and prevents norepinephrine's reuptake from the synaptic cleft. This may contribute to its clinical effects at higher doses.

Fluoxetine inhibits the cytochrome P450 CYP 2D6 and 3A4 enzymes via the parent compound and the active metabolite. The half-life of the parent compound is 2–3 days and that of the active metabolite is 2 weeks (Stahl 2008).

Specific Compounds and Properties

N-Methyl-γ-[4-(trifluoromethyl)phenoxy]benzenepropanamine hydrochloride.

Clinical Use (Including Side Effects)

FDA-Approved Clinical Uses

Fluoxetine is FDA-approved for the treatment of some mood and anxiety disorders. Mood

disorders include major depressive disorder (MDD), premenstrual dysphoric disorder (PMDD), and bipolar depression. Anxiety disorders include OCD and panic disorder, with or without agoraphobia (Lilly 2009).

In the treatment of mood and anxiety disorders, fluoxetine is usually started between 10 and 20 mg once daily and gradually increased to 20–80 mg daily in adults (Lilly 2009). The goal of treatment is complete remission of symptoms and prevention of future relapses, so fluoxetine is taken both throughout and in between clinical relapses (Stahl 2009). Fluoxetine does not cure mood or anxiety disorders, and symptoms can reoccur after the medicine has been stopped.

In adults with MDD, fluoxetine is used to treat acute depressive episodes and as maintenance therapy between episodes (Lilly 2009). After the first episode of depression, fluoxetine should be taken for 1 year (Stahl 2009). After the second or any subsequent episodes of depression, treatment with fluoxetine may be indefinite to avoid relapse of symptoms. Fluoxetine has also been helpful in the short-term treatment of acute depressive episodes associated with bipolar I disorder when used in combination with olanzapine (Lilly 2009). Combination therapy with set doses of fluoxetine and olanzapine is manufactured as Symbyax by Eli Lilly, although these two medications can be prescribed separate from each other. Separate dosing may allow for more flexibility on the part of the prescribing clinician. Fluoxetine should not be used as monotherapy for treatment of depression associated with bipolar I disorder. The combination of fluoxetine and olanzapine is also indicated for treatment-resistant depression, referring to depression that does not respond to two separate trials of different antidepressants of adequate doses and duration within the current episode. A once-weekly dosing of fluoxetine is marketed as Prozac Weekly for the treatment of MDD.

In adults with OCD, fluoxetine is given to treat acute episodes and as maintenance therapy between episodes. Fluoxetine is also used in the acute treatment of adults with panic disorder, with or without agoraphobia. Fluoxetine can be helpful in the treatment of bulimia nervosa, an eating

disorder. Moderate to severe bulimia nervosa, which is defined as three bulimic episodes per week within 6 months, has been shown to benefit from treatment with fluoxetine. For bulimia, fluoxetine is dosed between 60 and 80 mg daily and patients may require indefinite treatment (Stahl 2009).

Regarding children and adolescents, fluoxetine is FDA-approved for the treatment of MDD in pediatric populations aged 8–18 years and OCD in those aged 7–17 years (Lilly 2009). In MDD, fluoxetine is given for acute depressive episodes and as maintenance therapy between episodes. The starting dose is typically between 10 mg and 20 mg/day. Due to higher plasma levels in lower weight children, the target dose may not exceed the initial dosage or much beyond. In OCD, fluoxetine is given for acute episodes and as maintenance therapy between episodes. The starting dose is typically 10 mg/day, increased to as high as 60 mg/day in adolescents. Lower weight children may only tolerate a lower target dose, such as 20 mg/day.

Clinical Uses of Fluoxetine in Autism Spectrum Disorders

Regarding pediatric populations, there is limited evidence to suggest the effectiveness of fluoxetine in children and adolescents with autism. Interestingly, antidepressants have been the most commonly prescribed psychotropic medications in treating symptoms associated with ASDs (Aman et al. 2005). Given the frequent use of SSRIs in autism, it is imperative that prescribing clinicians balance the benefit of such medications in lieu of their side effects. In 2004, the FDA released safety warnings about the increased risk of suicide-related behaviors in children and adolescents taking SSRIs, which subsequently curtailed the prescribing of SSRIs to this population (Nemeroff et al. 2007). The decision to use fluoxetine in the treatment of established clinical indications that may co-occur with autism should therefore be made on an individual basis by the treating practitioner after careful consideration of the available data.

In the only published double-blind, placebo-controlled trial using fluoxetine to treat symptoms

associated with ASDs in children and adolescents, fluoxetine was found to be significantly better than placebo in reducing repetitive behaviors (Hollander et al. 2005). There was no improvement on measures of speech or social interaction, and side effects were not significantly different between fluoxetine and placebo. This study used low doses of liquid fluoxetine in a population of 45 children between the ages of 5 and 16 years (mean age, 8.2 years) who met criteria for autism, Asperger's disorder, or PDD-NOS. The starting dose began at 2.5 mg/day and was increased weekly to the target dose of 0.8 mg/kg/day, although the highest dose given was 0.4 mg/kg/day. Unfortunately, the remaining research in this area has been open label or retrospective, limiting further conclusions about the effectiveness of fluoxetine in treating children and adolescents with ASDs. There is no data regarding the effect of fluoxetine on anxiety, depression, hyperactivity, inattention, irritability, or aggression in children with ASDs.

In adult populations, there is minimal data supporting the use of fluoxetine in the treatment of ASDs as evidenced by only one small, placebo-controlled pilot study. This trial focused on six adult patients, five of whom had autism and one with Asperger's disorder (Buchsbaum et al. 2001). The patients showed significant improvement of anxiety and obsessive-compulsive symptoms while on fluoxetine. There was no significant improvement in depression. The starting dose was 10 mg daily, which was gradually titrated up to 40 mg daily in most of the patients. One should be cautious in applying these findings to the greater population of adults with autism as the small number of patients included in the study limits its interpretation. Unfortunately, there is no data regarding the effect of fluoxetine on hyperactivity, inattention, irritability, aggression, or social impairment in adults with ASDs.

It should be noted that the repetitive thoughts and behaviors observed in individuals with ASDs are qualitatively different from the symptoms of OCD (McDougle et al. 1995). For example, individuals with ASDs are more likely to experience compulsions of ordering, hoarding, telling or

asking, and touching, tapping, or rubbing. They are less likely to experience obsessions of contamination, sexual, religious, symmetry, or somatic content, unlike individuals with OCD. In the study of fluoxetine cited above, participants were rated on symptoms of OCD but no distinction was made regarding which repetitive behaviors improved.

Side Effects

Fluoxetine's side effect profile results from the stimulation of serotonin receptor subtypes as well as lesser actions on other neurotransmitters and enzymes. Stimulation of serotonin receptor subtypes (5-HT_{2A}, 5-HT_{2C}, 5-HT₃, and 5-HT₄) in various parts of the brain likely causes many of SSRIs' observed side effects (Stahl 2008). A small amount of increased synaptic serotonin shortly after initiating therapy is often enough to mediate side effects, even if the clinical benefit is not yet apparent to the patient. Therefore, it is possible that side effects may be experienced earlier than symptom relief when first starting treatment with fluoxetine (Stahl 2008). Side effects experienced may also be dose dependent (i.e., they increase as the dose increases) or time dependent (i.e., they start right after taking the medication but diminish with time) (Stahl 2009).

Patients who are treated for MDD are at increased risk for experiencing suicidal thinking and behavior. Antidepressants as a class have been shown to increase the risk of suicidal thinking and behavior in children, adolescents, and young adults (ages 18–24) with MDD and other psychiatric disorders. Such risk should be carefully considered when prescribing fluoxetine in the pediatric and young adult population. According to Stahl (2009), gastrointestinal side effects are common and can include decreased appetite, nausea, diarrhea, constipation, or dry mouth. Sexual dysfunction is a common side effect in both men and women and is due to the effect of increased serotonin in both the brain and the region of the spinal cord regulating sexual response. In men, this includes delayed ejaculation, erectile dysfunction, and decreased sexual desire. In women, this includes decreased sexual

desire and anorgasmia. Central nervous system side effects include insomnia or sedation, agitation, tremors, headache, and dizziness or lightheadedness. Patients may experience vasodilatation, dry mouth, diaphoresis, or abnormal vision. Increased serotonin can lead to diminished dopamine release, which may lead to emotional flattening, apathy, and cognitive slowing in some patients. Anorexia and weight loss have been reported when using fluoxetine, so it should be used with caution in underweight patients or those who are prone to eating disorders (Lilly 2009).

Of note, SSRIs have been found to yield side effects in people with ASDs, particularly agitation, hyperactivity, aggression, and insomnia (Posey et al. 2006). Extrapyramidal symptoms (Sokolski et al. 2004) and hypomania (Damore et al. 1998) have also been observed in case reports. These results are limited by a lack of placebo-controlled studies, although there is some evidence to suggest that children with ASDs may be more likely to develop such side effects relative to adults with ASDs (Posey et al. 2006).

Synonyms

Fluvoxamine maleate; Luvox; Luvox CR

Indications

Fluvoxamine is FDA-approved for the treatment of obsessive-compulsive disorder (OCD).

Mechanisms of Action

Fluvoxamine is a selective serotonin (5-HT) reuptake inhibitor (SSRI). Its efficacy in the treatment of OCD is thought to result from inhibition of the serotonin reuptake process and increased serotonergic neurotransmission (Stahl 2008).

Fluvoxamine primarily inhibits the oxidative drug-metabolizing enzyme CYP1A2 and also significantly inhibits CYP3A4, CYP2C9, and CYP2C19. It is a weak inhibitor of CYP2D6 (Irons 2005; Kuzma and Black 2008). Additionally, it is a sigma-1 receptor agonist (Ordacgi et al. 2009). Sigma-1 receptors regulate the release of glutamate, dopamine, serotonin, norepinephrine, and acetylcholine. Fluvoxamine's high affinity for these receptors may account for some of its effects on depression and anxiety.

Specific Compounds and Properties

Fluvoxamine maleate has the International Union of Pure and Applied Chemistry (IUPAC) name (E)-5-methoxy-1-[4-(trifluoromethyl)phenyl]pentan-1-one *O*-2-aminoethyl oxime maleate and the empirical formula $C_{15}H_{21}O_2N_2F_3 \cdot C_4H_4O_4$ (Fig. 1).

Fluvoxamine is metabolized by the liver into at least 11 products, all of which are pharmacologically inactive. It is excreted primarily as metabolites, with less than 4% of the original compound remaining. The precise CYP isoenzymes involved in its metabolism are not known. There is evidence that fluvoxamine has nonlinear steady-state pharmacokinetics so that plasma concentrations are disproportionately higher when the dosage is increased. It has a mean plasma half-life of 12–22 h, which is increased by 30–50% at steady state. It has been demonstrated to be eliminated from the brain at a slower rate than from the plasma (2.4:1 ratio; Ordacgi et al. 2009).

In vitro studies have found it to be a stronger inhibitor of serotonin reuptake than fluoxetine, but weaker than paroxetine, sertraline, citalopram, and escitalopram. It is also a weak inhibitor of norepinephrine and dopamine reuptake when compared to other serotonin reuptake inhibitors (Ordacgi et al. 2009).

Clinical Use (Including Side Effects)

Luvox is the brand name of fluvoxamine maleate in the United States. It is available in both

immediate-release (IR) and extended-release (controlled-release; CR) tablets and is FDA-approved for the treatment of obsessions and compulsions in individuals with OCD. The IR form is approved for use in patients 8 years and older, while the lowest dosage of the CR form may not be appropriate for pediatric patients (U.S. Food and Drug Administration 2011a, b). Its efficacy in the treatment of OCD has been demonstrated in numerous randomized, double-blind, controlled studies. Fluvoxamine has repeatedly been shown to be more efficacious than placebo when measured by the Yale-Brown Obsessive Compulsive Scale (Y-BOCS), National Institute of Mental Health-Obsessive Compulsive (NIMH-OC) Scale, and Clinical Global Impression (CGI) scales (Ordacgi et al. 2009). Studies have also compared fluvoxamine to the tricyclic antidepressants clomipramine and desipramine. Fluvoxamine was found to be equally efficacious as clomipramine and more efficacious than desipramine in the treatment of OCD (Irons 2005). It has additionally been shown to be efficacious in the treatment of OCD in children and adolescents aged 8–17 years (Irons).

Luvox CR was initially approved for the treatment of social anxiety disorder, but this indication was removed from its label in 2011. However, a number of double-blind, placebo-controlled studies have shown promise for the treatment of social anxiety disorder with fluvoxamine. The results of several studies, two involving over 250 patients each, have demonstrated significantly greater improvements with fluvoxamine than with placebo, using measures such as the Liebowitz Social Anxiety Scale, CGI scales, and the Hamilton Anxiety Scale. Furthermore, fluvoxamine has been demonstrated to be significantly more effective than placebo in a study of 128 children and adolescents aged 6–17 years with social anxiety disorder, separation anxiety disorder, or generalized anxiety disorder (GAD) (Irons 2005).

Fluvoxamine may also be an effective treatment for some of the behaviors associated with autism. In a randomized, double-blind study with 30 adults, 53% of the patients treated with

Fluvoxamine, Fig. 1 Chemical structure of fluvoxamine maleate

fluvoxamine were classified as responders. There was a significant reduction in repetitive thoughts and behaviors, maladaptive behavior, and repetitive language usage in the fluvoxamine group compared to the placebo group (McDougle et al. 1996).

There have been mixed results in studies reporting the use of fluvoxamine for the treatment of autism in children. In one double-blind cross-over study of fluvoxamine and placebo, 10 out of 18 children were classified as responders, while in another, improvements were shown in behaviors such as eye contact and language use (Fukuda et al. 2001; Sugie et al. 2005). However, an open-label trial and a double-blind, parallel groups comparison with placebo, which both administered fluvoxamine to 18 subjects, classified only 3 and 1 subjects, respectively, as responders (Martin et al. 2003; McDougle et al. 2000).

Numerous studies of adults have shown benefits for the treatment of depression, panic disorder, GAD, and posttraumatic stress disorder (PTSD), for which fluvoxamine is also commonly prescribed (Irons 2005; Stahl 2008). Additionally, several randomized, double-blind studies have demonstrated fluvoxamine's efficacy in the reduction of binge eating, relapse of bulimia nervosa, compulsive buying, and pathological gambling (Irons).

The recommended starting dose of fluvoxamine is 25 mg in pediatric patients and 50 mg in adults, taken before bed. The dose should be increased every 4–7 days in 25-mg increments in children and 50-mg increments in adults until the maximum benefit is reached. The dose should not exceed 200 mg/day in children up to age 11 years and 300 mg/day in adolescents and adults. If the dose is more than 50 mg for the pediatric population or 100 mg for adults, it is recommended for it to be divided into two doses. With uneven doses, the larger one should be taken before bed (U.S. Food and Drug Administration 2011b).

Side Effects

The most common adverse reactions in trials with adults with OCD and depression include nausea, somnolence, insomnia, asthenia, nervousness,

dyspepsia, abnormal ejaculation, sweating, anorexia, tremor, and vomiting. Less frequent side effects include anorgasmia, decreased libido, dry mouth, rhinitis, taste perversion, and urinary frequency in individuals with OCD and agitation, depression, dysmenorrhea, flatulence, hyperkinesia, and rash in pediatric patients with OCD (U.S. Food and Drug Administration 2011b).

As with other antidepressants, fluvoxamine may result in the worsening of depressive symptoms and an increased suicide risk. It should not be used in combination with monoamine oxidase inhibitors or within 14 days of ending treatment with one. Additionally, tizanidine, thioridazine, alosetron, and pimozide should not be coadministered with fluvoxamine. Serotonin syndrome and neuroleptic malignant syndrome have also been reported with SSRIs, including fluvoxamine. There is evidence that the CR form has a lower maximum plasma concentration, reducing the risk of adverse effects (Ordacgi et al. 2009).

Food Intolerance

Susan Hyman

Developmental and Behavioral Pediatrics,
Division Chief Neurodevelopmental and
Behavioral Pediatrics, University of Rochester
Golisano Children's Hospital, Rochester,
NY, USA

Definition

Food intolerance refers to the occurrence of physical symptoms relative to ingestion of foods that are not the result of conventional IgE-mediated food allergy. IgE is the subclass of immunoglobulins that cause an individual to make antibodies to food or other compounds that result in allergic symptoms. Food intolerance may be more common than true food allergy. The physical symptoms of food intolerance may impact the skin and the gastrointestinal and respiratory tracts. Central nervous system symptoms like migraines may occur. Food intolerance may manifest in a delayed fashion, unlike IgE-mediated allergy. Food intolerance is attributed to the following mechanisms:

1. Absence of an enzyme necessary for metabolism of an ingested food: An example of this is lactose intolerance. Approximately 10% of Americans are intolerant of the milk sugar, lactose, because of an absence of the enzyme necessary for digestion with resultant symptoms of diarrhea, bloating, and intestinal gas.
2. Symptomatic response to a food or food ingredient based on genetic susceptibility: An example of this is intolerance of natural salicylates. Salicylic acid is the active ingredient in aspirin. Approximately 2.5% of Europeans are intolerant of natural salicylates found in various fruits and vegetables. Other chemicals in food that are associated with intolerance include food additives like monosodium glutamate, nitrites, and artificial food colors.
3. Symptomatic response to a chemical compound in food based on a co-occurring condition: An example of this is development of

physical symptoms relative to histamine ingestion when the enzymatic degradation of this vasoactive amine is impaired by an imbalance of intestinal flora or a medication prescribed for another condition.

4. Non-IgE-mediated immune response: The utility of measuring IgG to foods is controversial and at present does not guide therapy.

Food intolerance needs to be clinically distinguished from IgE-mediated food allergy. This is done by history and physical examination, allergy testing, elimination diets, and double-blind food challenges. Unlike food allergy, many people with food intolerance do not have symptoms with small and infrequent exposures. Dietary avoidance is the treatment.

Families of children in Norway later diagnosed with autism spectrum disorders report more food allergies and intolerance in the first 3 years of life (Bresnahan et al. 2015).

Formal Complaint

Margaret St. John

Quinnipiac University School of Law, Hamden, CT, USA

Definition

Formal Complaint

In General

A formal complaint is an initial filing that starts a civil lawsuit and usually states the basis for a court's jurisdiction, the basis for a plaintiff's claim, and a demand for relief.

Individuals with Disabilities Education Act

Individuals (typically parents) may submit a formal complaint to a child's school district and/or state education agency alleging violation of the Individuals with Disabilities Education Act.

Any party has an opportunity to present a formal complaint regarding the identification, evaluation or educational placement (IEP) of a child, or the provision of a free appropriate public education (FAPE) to such child. The complaint must be filed within 2 years of the date when the parent or public agency knew or should have known about the alleged action that forms the basis of the complaint.

When filing a complaint alleging that a local educational agency has violated a requirement of the Individuals with Disabilities Education Act, the complaint must be written, signed, and must cite the facts upon which the allegation is made and the specific statutory requirement that was violated. The state educational agency must resolve the issues of the complaint within 60 days after it is filed.

Americans with Disabilities Act

If an individual believes that he or any other person has suffered discrimination, he may file a complaint with the Department of Justice. Such a complaint should include contact information, the name of the business, organization, institution, or person that perpetrated the alleged discrimination and a description of the discrimination.

France and Autism

Bernadette Rogé
 CERPPS, Université Toulouse Jean Jaurès,
 Toulouse, France
 CeRESA (Centre Régional d'Education et de
 Services pour l'Autisme), Institut Universitaire de
 France (IUF), Toulouse, France

Historical Background

The first approach to autism in France was based on the psychoanalytic model, in terms of etiology

as well as in treatments. Regarding etiology, the parents' role in the pathology's development was emphasized leading to treatments based on that interpretation. Therefore, in the extent that the child's autism was supposed to be due to relational difficulties, psychotherapy prevailed for many years. There were mostly institutional interventions, implemented in day hospitals. They were initiated by psychiatrists such as Roger Misès and Serge Lebovici. Despite the assertions that psychoanalysts used a multifactorial approach, the treatments were essentially psychological leaving little room for educational aspects. Above all, they preferred a nondirective attitude saying that it was better to wait for "the emergence of desire" rather than to provide teaching. The parents were not directly involved in their child's treatment and had to personally undergo psychotherapy. Only a few facilities took the different dimensions of autism into account and carried out more complete medical explorations. However, in most cases this did not have a real impact on treatment. At the time, parents were not well informed on autism and when the first parent association, ASITP, was founded in the 1960s, it mainly focused on establishing new day hospitals in which this type of approach was implemented.

In France, Gilbert Lelord, who passed away early in the year 2017, was the great pioneer of the scientific approach to autism. He was surrounded by a team of clinicians and researchers among who Catherine Barthélémy, his most brilliant collaborator, gave a quality extension to his initial work. This team largely contributed to changing the image of autism in France by defending the biological cause of this condition. Numerous studies carried out by the INSERM 316 unit have demonstrated that childhood autism is not a psychological pathology but linked to a developmental disorder of the nervous system. Clinicians gathered extensive patient information while providing support to families. Collaboration with the research team resulted in creating the first standardized tools for assessment of children with autism (Barthélémy and Gilbert 1991; Rogé 2017). The different research protocols helped to better understand the

neurophysiological functioning and to determine subgroups of patients. All of this work and research underpinned the reflection on a new therapeutic approach, which culminated with the development of exchange and development therapy (Barthélémy et al. 1995). Parent associations have also significantly contributed to the improvement of people with autism's situation in France even though they initially opposed one another, some continuing to defend the psychiatric approach, while others, very militant, demanded an adapted education like those advocated in most other countries.

In the 1990s, things began to change. Government authorities finally took parents' repeated requests into account. Various commissions were organized. From then on, the French classification of Mental Diseases CFTMEA (1993), which still classified autism in infantile psychoses, was abandoned by the Ministry of Health. The World Health Organization's CIM10 became the new classification reference. At that time, three major diagnostic centers were recognized, one in Tours, one in Toulouse, and one in Paris. Subsequently resource centers were created and later developed throughout France. The specific way in which individuals with autism function was finally acknowledged and new units delivering behavioral and developmental programs were created. In 1995, Simone Veil, Minister of Social Affairs, Health and the City, adopted a 5 year, 100 million francs (approximately seven million dollars) plan of action for autism. The problem of the exclusion of individuals with autism was brought before the Council of Europe. In 1996, the Chossy Act was voted, which assigns a disability status to autism and guarantees these individuals the right to access care in a multidisciplinary approach. In 2003, Deputy Chossy reported to the government denouncing the situation of individuals with autism and called for a plan of action to enforce their rights. Despite all these efforts, France remained behind. Parents of "Autism France" took up action before the European Court of Justice which condemned France on several occasions for failing to respect the right to education of individuals with autism. This will be

followed by recommendations for diagnosis, the 2005 Disability Act, which guarantees equal rights and opportunities, the referral to the National Ethics Advisory Committee in 2007, which highlights the lack of care and the resulting distress in families, recommendations for a scientifically validated intervention, and three autism action plans that allowed new funding to be allocated to developing the first Resource Centers and specific interventions. In 2012, autism was declared Great National Priority, leading to various awareness-raising campaigns and strong media coverage. Recommendations on intervention for adults are currently being developed and an international scientific committee has been set up to determine what the main axes of the fourth autism action plan should be.

Legal Issues, Mandates for Service

The disabilities Act of 11 February 2005 and Decree No 2005-223 of 11 March 2005 defines the goals of support services in social and medical institutions. This Act aims to improve inclusion of individuals with disabilities. Based on the principle of equality, the act recognizes that a disabled person's right to compensation is a societal duty and is not dependent on appeal to pity or charity. It aims to restore equal opportunities for all citizens. Among other things, this Act resulted in the increase of requirements regarding accessibility to urban areas and access to employment for disabled individuals. A National Solidarity Fund for Autonomy (CNSA) was established to finance this Disabilities Act, but it is not specifically dedicated to autism.

After the enactment of the Chossy Law in 1996, various parent association actions led the government to define a new policy in favor of autism through successive autism action plans.

During the first plan of action from 2005 to 2007, Autism resource centers are created. Their main tasks are to inform and guide the affected people and their families. They must organize diagnoses and multidisciplinary assessments of children and adults, develop individual

evaluations in order to establish a personalized project for each person, facilitate contact and information within professional circles, and develop local documentation centers. Improvement in parent and professional training is planned. Adapted services are developed but still extremely insufficient. The plan of action also advocates better schooling for children with autism in mainstream classrooms.

The second autism plan of action between 2008 and 2010 provided 4100 openings in services for children and adults with autism. The High Authority for Health (HAS) had the task of creating an international, scientific, and multi-disciplinary database which would serve as a reference. Together with the National Agency for the Evaluation and the Quality of Social and Medical Social Establishments and Services (ANESM), they must define guidelines on good practice in the field of autism.

The third autism plan of action organizes early diagnosis and intervention. It stresses the importance of lifelong support with schooling for children and social and professional inclusion for adults. Better support for families is advocated and the resource centers are responsible for organizing it. The action plan also calls for continued efforts to support research on the origins of autism, the mechanisms involved, indicators facilitating early diagnosis, evidence-based treatments, and actions promoting social inclusion.

These three Autism Action Plans have helped improve common knowledge on autism and have attempted to change practices. They made it possible to affirm that psychoanalysis was not a treatment for autism and promote scientifically validated treatments. Resources have been allocated to developing quality services for patients and their families as well as to research. Nevertheless, the situation remains critical as not all the measures planned by the government have been implemented. Many families are still struggling to find suitable services. Despite government recommendations, the services provided in each region vary greatly. While many professionals have turned to scientifically validated practices, others remain on old positions and continue to apply methods that

families no longer want. The Autism Action Plans generated substantial funds yet they are still insufficient to adequately assist people with autism and their families in France.

A fourth Autism Action Plan is being considered. The main aim should be to reinforce the progress of the previous action plans. The current minister organized a committee of international experts to support her approach. A new government was elected in 2017. It is committed to continuing efforts for people with autism. The 4th autism plan should focus on continuity of care at all ages and develop new facilities for adults with autism. Real progress can only be achieved through ground breaking decisions such as allocating financial aid based on compliance with recommendations and the application of scientifically validated practices.

Overview of Current Treatments and Centers

Due to the long history of psychiatric medicalization in France, services for individuals with autism primarily depend on the Ministry of Social affairs and Health. This Ministry delegates the organization of services to a ministry under its supervision: Ministry of disabled people and the fight against exclusion. The ministries of education, labor, cities, youth, and sports are secondarily involved, usually for specific actions or for creating partnerships.

Therefore, the Ministry of disabled people and the fight against exclusion plays the primary role in organizing services. A national solidarity fund was established to finance care services, but it is not specific to autism. It covers all disabilities as well as assistance to the elderly.

Two national agencies, ANESM (National Agency for the Evaluation and the Quality of Social and Medical Social Establishments and Services) and HAS (High authority of Health) are responsible for monitoring the quality of services and have initiated a process of reflection leading to recommendations on good practice in cooperation with parent associations and experts in autism. This has helped the situation in France

evolve. There is a better understanding of autism and new services correspond more accurately to the needs of individuals with autism. Nevertheless, widely disseminating this knowledge is necessary to change the outdated services and develop new options for people with ASD.

On a regional level, local health agencies publish calls for projects based on the development policy launched by the Ministry. They open up the competition to project promoters which can either be associations or hospital services. They receive funds from the CNSA (National Solidarity Fund for Autonomy) and attribute these funds to the selected projects. They then monitor the use of allocated resources.

The MDPH (Departmental Office of disabilities) manages orientations. Its teams assess and determine the degree of disability and orient towards available services. The disability rate opens rights to financial compensation allowances (AEEH = disabled child education allowance and AAH = adult disability allowance) for disabled people and a possible compensatory allowance (PCH = Disability Compensation Benefit). The commission that allocates financial aid (Committee on rights and autonomy of persons with disabilities = CDAPH) consists of only professionals but service users are represented by parent associations. Resource centers inform families and professionals about services.

Services for Children

For children and adolescents with disabilities, the right to education is associated to an obligation of schooling or appropriate support. It can be implemented within the schools' "ordinary" classrooms. Enrollment in the mainstream is favored with adaptations (teacher's aid, teacher, and staff training). Schooling can also be implemented in a collective arrangement School Integration Classes – CLIS – or Localized Units for Inclusive Education – ULIS – in higher education. Enrollment can be full-time or part-time with the support of a specialized institution if needed. Self-contained classrooms for children from 3 to 6 years of age were recently created in preschool. These classes are opened to a small number of children (maximum seven) who could not be

enrolled despite the help of a teachers aid. In these specialized classrooms, a multidisciplinary team applies a personalized program for each child. They also benefit from inclusion in regular classrooms (mainstreaming) therefore attending school full-time.

Different Specialized Structures Can Take Care of Children with Autism

For young children with sensory, motor, or mental deficits up to the age of 6, CAMSP (Early medico-social centers) are involved in the early detection of disability, outpatient treatment, rehabilitation, and family-directed services. They offer consultation, rehabilitation, as well as individual or group activities promoting child development and social integration. With parental consent, concerted actions can be carried out in the child's natural environment (day care centers, school, or recreation center).

For children able to attend school, different outpatient services are available: CMP (Medico-psychological centers) are consultation services for people in need of psychological support. There are infant-juvenile CMPs for children and adolescents up to 16 years of age. The care is free and multidisciplinary. CMPP (medical psychoeducational centers) are in charge of diagnosis and treatment in outpatient care for children aged 3–18 or 20 years, suffering from neuropsychiatric disorders or behavioral disorders. Treatments are individual psychotherapy, psychotherapy, family therapy, speech and language rehabilitation, and psychomotor therapy. The child or adolescent stays in his family, school, and social environment. A SESSAD (Special Education and Home Care Services) aims to enable children with various disabilities within their natural environment allowing them to continue developing in their family and social environment. The multidisciplinary team's main goal is the early management of the child, family-directed services, academic support, and self-help skills. Services can be provided in the child or adolescents natural environment. Early intervention SESSAD programs have recently been established. They can accommodate children starting from 18 months who can benefit from programs like the ESDM.

Day hospital institutions take care of patients on a full-time or part-time basis during the day. A team composed of psychiatrists, psychologists, speech therapists, occupational therapist, educators, and social workers care for the patient. Usually special education classrooms are implemented in the day hospital but are not a priority over treatment. Some day-hospitals include mainstreaming.

The other structures care for children and adolescents with intellectual disabilities on a full-time basis regardless of the degree of their disability. IME (Medical-Educational Institutes) regroup several categories of structures: "Medical-Pedagogical Institutes" (IMP) provide full residency, semi-boardings, temporary reception or day schooling for children aged 3–6 to 14 years old. Medical-Professional Institutes (IMPRO) accept children and adolescents ranging from 14 to 20 years old. Here they receive health and educational care through a therapeutic and pedagogical approach supposed to promote the development of the child or adolescent. The acquisition of autonomy skills (transport, management of a budget, etc.) and preprofessional training are also important goals. IMPROs provide vocational training (which may lead to a Diploma) for integration into the protected or ordinary work environment. ITEP (Therapeutic, educational, and pedagogical institutes) are medical-social structures which take in children and adolescents with intact intellectual and cognitive potential but who present psychological difficulties and behavioral disorders which severely disrupt socialization and access to learning. The different autism action plans favored the creation of experimental structures in which behavioral and developmental models are applied in accordance with the recommendations of the High Authority of Health. Parents hope that this type of structure will continue to develop.

The structures caring for children with disabilities are therefore numerous and diverse, but they are often inadequate for children with autism. Therapeutic approaches are often unspecific due to the lack of professional training. This situation is changing through the different autism action plans, but many parents are still unhappy with

what is being offered and availabilities in the structures applying the recommendations of the HAS are still insufficient. As a result, many children are on waiting lists with no options. Parents, who have no other alternative or who do not agree the institutions approach, can call on psychologists and educators who work in private practice. However, this represents a significant cost, sometimes preventing the child to access sufficient treatment, whereas the treatments in institutions are paid for by the state.

Services for Adults

Services available to adults are either in the health or in the medical-social field. In the psychiatric services of the health sector, people with autism are often mixed with patients having various psychiatric pathologies; therefore, their specific needs are not met. They may also suffer from the violence of other psychiatric patients. Some professionals have become aware of this serious problem and have organized smaller units for people with autism. However, generally these adults are often left on their own, without specific support causing many behavioral disorders.

In the medical-social sector (with or without identified specific services for autism), there are different structures. MAS (Specialized Care Homes) receive disabled adults who have acquired little autonomy and whose condition requires medical supervision and constant care. These specialized care homes or MAS are nursing homes. They can accommodate people with multiple disabilities, usually with a severe mental disability or people who acquired disabilities (brain injury). Some MAS also welcome people with autistic syndromes but do not provide specialized treatment. Generally, MAS provide year-round accommodation, day care services, or temporary accommodation. Those being cared for in a MAS lack autonomy and are unable to care for themselves in daily life responsibilities. Assistance is needed for activities of daily living and for health monitoring. In general, people accommodated in MAS have less autonomy than those in other health and welfare services for disabled adults (foster home or medicalized foster home), but MAS residents

are not within the psychiatric sector. A person admitted to this structure may end his days there. The MAS are financed by health insurance funds, therefore the services of the regional health agencies (ARS).

Adult Foster Homes (FAM) are nursing homes. They welcome people with multiple disabilities, severely disabled adults unfit for any professional activity who need assistance with daily living tasks or medical monitoring. They can also accommodate seniors with disabilities. Generally, FAM residents have more autonomy than those in the specialized care homes (MAS). Medicalized FAMs are funded in part by health insurance, for care and medical staff, in part by the departmental council, for accommodation and entertainment. That is why the FAM were also called “dual pricing home.”

There are other forms of accommodation which depend on a person's level of autonomy. Living spaces or homes are very small structures providing a personalized support. Legally, these are not social institutions or services. However, they are obligated to implement individual life projects, taking into account the resident's expectations and needs.

Group homes for disabled adults provide accommodation and care for disabled individuals who work in either an ordinary environment, an institution, a support service through work (ESAT), or an adapted enterprise during the day. Foster homes offer accommodation, care, and medical assistance for physically or mentally disabled working adults. A SAMSAH (Medical and medical-Social support services for Disabled Adults) tries to maintain people with disabilities in the mainstream, by helping restore social ties (family, school, business, etc.) and promoting access to services offered by the community. In addition to these benefits, they provide medical assistance. Temporary Homes for disabled adults have several objectives: first of all, they allow the disabled person to change his or her living environment and if necessary, escape from time to time to avoid the risk of confinement; secondly, they allow “caregivers” to benefit from respite time. Temporary stay is organized for a limited period of up to 90 days per year, full or part time,

with or without accommodation, including day care. It can be arranged in a sequential mode, that is, to say by programmed periods throughout the year.

For the most autonomous, services are organized to allow access to employment.

Support services through work (ESAT), formerly called CAT (Centre for assistance through work), provide services to disabled adults with a working capacity of less than one third of the normal capacity to take up employment in an ordinary environment. Vocational Rehabilitation Centers provide training for disabled adults to facilitate integration or reintegration into either an ordinary or protected working environment. A SAVS (Accompanying Service for accessing society) is a structure that assists disabled adults in fulfilling their life project by helping maintain or restore family, social, academic, or professional ties and by facilitating access to community services and events.

Experimental Facilities for disabled adults are aiming to promote new types of support, organize a more rational way to access to the care system facilities, a better coordination of this support, as well as training and prevention for behavior disorders and health issues.

There are therefore many structures in France for adults with disabilities. Unfortunately, they are rarely suitable for people with autism. The different autism action plans have partially corrected this situation, but there is still a lot to be done in order to provide all adults with the assistance that suits their specific needs. Too many people are still left with no options in France. These individuals live in their parents' home. This is an important issue because aging parents, struggling to handle the situation, are concerned about the future of their child and what will happen when they are no longer around.

Overview of Research Directions

In France, a majority of the research units belong to large organizations such as the CNRS (National Center for Scientific Research) and INSERM (National Institute for Health and

Medical Research or Institut Pasteur). These units are located in university hospitals, universities, or specific institutes. Other laboratories are part of universities.

Thomas Bourgeron's team at Pasteur Institute works on the genetics of autism and sleep disorders related to melatonin production. This team found several genes involved in autism, such as SHANK1, SHANK2, SHANK3, and NRXN1, which also play a role in the transmission of neuronal information. These researchers also proposed a murine model of autism (Jamain et al. 2003; Durand et al. 2007; Delorme et al. 2013; Bourgeron 2015).

The Fundamental Foundation supports research in psychiatry, including research in the field of high-functioning autism. The teams of the Asperger Experts Centers of Créteil and Robert Debré recently published a study comparing high-level autism and schizophrenia in Multimodal MRI. The results reveal the coexistence of common and opposite susceptibility factors in these two pathologies (Katz et al. 2016). InFoR-Autism is a new project whose objective is to study patients' clinical and cognitive profiles to look for biomarkers (clinical, neuroanatomic, immunological, and biochemical) and to identify genetic factors involved in autism. The establishment of a 2-year cohort follow-up of patients, healthy subjects, and relatives (parents, brothers, or sisters of the patients included in the study) is planned.

An INSERM team in Tours pursues research on the evaluation tools and the neurophysiological mechanisms involved in autism. Their main research uses MRI, EEG, and eye tracking. These technologies are used to study the maturation of human face exploration (Aguillon et al. 2016), the differences between ASD and Mental deficiency (Bonnet-Brilhault et al. 2016), and atypical brain mechanisms in ASD (Thillay et al. 2016). Currently, the team is engaged in a new project "Emotional Attention and Attention Related to Change in Autism."

Other examples of research carried out by university teams are eye-tracking research (Guillon et al. 2014, 2015, 2016), research on the effect of slowing down movement of what will be

perceived (Tardif et al. 2007), and research on screening (Baduel et al. 2016). New research directions include treatment evaluation and cost-effectiveness studies.

It is impossible to cite all the research teams here and these are merely examples, but although France has lagged behind in the implementation of adapted treatments, there are some interesting achievements in the field of research. Public funds for research are, however, rather limited and researchers must solicit private foundations and contributors. Involvement in international programs, particularly in Europe (e.g., Salomone et al. 2015), reinforces French research. Recently INSERM created the Autism Research Network that will bring together the efforts of different teams and strengthen their resources. This initiative will hopefully increase knowledge and enhance practices on autism.

Overview of Training

The training of professionals in France is very inadequate. In physicians' training, only a small part of the curriculum focuses on autism, except for university centers where specialists and researchers work in neurodevelopmental disorders. In psychology departments, curriculums vary greatly from one university to another and some professors still teach old models of autism highlighting psychoanalysis. Fortunately, some researchers teach courses that are up to date and correctly train their students. The same problem exists in the various institutes that train educators, social workers, speech therapists, and occupational therapists. In order to compensate their lack of specific training, continuing education qualifications have been created. After graduation they can receive an up-to-date training. Associations have also created training courses to complement professional training.

Social Policy and Current Controversies

The current government intends to maintain its efforts to develop adapted services in the next

autism action plan. Progress is still needed in early diagnosis and intervention as well as in appropriate services for school-aged children, adolescents, and adults, and parents are fighting for this. However, France is still lagging behind and budgets are limited. In addition, some teams still refuse to follow HAS recommendations. Training needs to be profoundly modified so that all medical professionals have solid knowledge on autism and are able to diagnose it as early as possible. Other professionals should be able to implement appropriate treatments. It would also be important for the general public to be better informed in order to help encourage the inclusion of people with autism in society.

Fraternal Twins

► Dizygotic (DZ) Twins

Fred R. Volkmar

Gerrit Ian van Schalkwyk
Department of Psychiatry, Yale School of Medicine, Yale Child Study Center, Yale University, New Haven, CT, USA
Butler Hospital, Brown University, Providence, RI, USA

Name and Degrees: Volkmar, Fred R.

- B.S., University of Illinois, with high honors (1972)
- M.A. (psychology), Stanford University (1976)

- M.D., Stanford University School of Medicine (1976)
- M.A. (Hon), Yale University (1999)
- D.Sc. (Hon), University of Illinois (2013)

Major Appointments

- Director, Yale University Child Study Center, New Haven, CT (2006–2014)
- Chief of Child Psychiatry, Yale New Haven Hospital, New Haven, CT (2006–2014)
- Irving B. Harris Professor of Child Psychiatry, Psychiatry, Pediatrics, and Psychology, Yale University, New Haven, CT
- Director, Autism Program, Yale University Child Study Center, New Haven, CT (1983–2006)

Major Honors and Awards

- International society for Autism Research Lifetime Achievement Award, Atlanta, GA, 2014
- Distinguished Contributor to the Field Award, Autism Services & Resources Connecticut, 2014
- Frank J. Menolascino Award for Work in Developmental Disabilities, American Psychiatric Association, Philadelphia, 2013
- Honorary Doctor of Science, University of Illinois, 2013
- Lauretta Bender Award, New York State Psychiatric Institute, 2012
- George Tarjan Award for Research in Developmental Disabilities, American Academy of Child and Adolescent Psychiatry, 2007
- Emily and Frank M Puzio Award, Eden Institute Foundation and Princeton Lecture Series, 2007
- Blanche F. Ittleson Award, American Psychiatric Association, 1997

Landmark Clinical, Scientific, and Professional Contributions

- Over \$10 million in grants from the NIH, including for the projects “The Social

Neuroscience of Autism and Related Disorders” and the “Neurobiology and Genetics of Autism and Related Conditions”

- Over 200 articles in peer reviewed journals, including the seminal papers “Seizure Disorders in Autism (1990)” and “Field trial for autistic disorder in DMS-IV”
- Over 150 book chapters and editor of multiple books on autism spectrum disorders
- Extensive service on local, national, and international committees including the APA Child and Adolescent Disorders Work Group for DSM-IV, the Committee on Disorders of Infancy and Early Childhood for DSM-IV (chair), and the APA Disorders of Infancy Work Group for DSM-5. On advisory board for Autism Genome Project since 2006 and reviewer for multiple organizations including the NIMH, Wellcome Trust, Autism Speaks, and the Medical Research Foundation of the UK
- Editor of the Journal of Autism and Developmental Disorders, the Encyclopedia of Autism, and the definitive “Child and Adolescent Psychiatry: A Comprehensive Text”

Biography

Fred Robert Volkmar was born in Illinois in 1950 and received an undergraduate degree in psychology from the University of Illinois in 1972. He then attended Stanford University where he graduated with both an M.D. and a master’s degree in psychology. During his time at Stanford, he was engaged in basic science research studying dendritic branching in rats, with the first publication of his career appearing in the journal *Science*. Dr. Volkmar then completed a psychiatry residency at Stanford before coming to the Yale Child Study Center for a fellowship in Child and Adolescent Psychiatry. He remained at Yale for the duration of his career, where he founded the Developmental Disabilities Clinic in 1982 and engaged in landmark research which spanned from efforts at

understanding the basic neuroscience of ASD to clinical research exploring the implications of changes in the definition of autism and related disorders over time. Dr. Volkmar led the DSM-IV field trial to develop the diagnostic criteria for autism and Asperger’s syndrome – this work was critical in bringing the diagnosis of Asperger’s into the public consciousness. Dr. Volkmar cofounded an undergraduate course on autism that was the first of its kind in the world and continues to be offered at Yale every year. Dr. Volkmar was the director of the Yale Child Study Center for 9 years, following which he returned to clinical work, teaching and research in the department as the Irving B Harris professor of Child Psychiatry, Psychology, and Pediatrics. Dr. Volkmar has an extremely impressive legacy of mentorship, having mentored many now-famous ASD scholars such as Ami Klin, Christopher McDougle, and James McPartland. Dr. Volkmar is married to Lisa Weisner and has two daughters.

Free Appropriate Public Education

Juli Katon

Department of Special Education, University of Maryland, College Park, MD, USA

Definition

Free appropriate public education (FAPE) is a term that is used to describe the federal mandate that all school-aged special education students be provided with special education and related services at public expense. The word “free” means that the individual is entitled to daily schooling at no extra cost to the family. The word “appropriate” means that the student’s education must be individualized to the unique learner’s needs as decided upon during the development of the student’s individualized education program (IEP). The word “public” refers to who will be paying for, supervising, and directing the learner’s education. The word “education” means that children who qualify for special education are entitled to schooling like their same-aged, typical peers. The services provided under FAPE must meet the standards of the local state education agency in addition to being provided at public expense to school-aged children from preschool to high school in accordance with the IEP.

For children with a diagnosis of autism, this means that the majority of their weekdays from the time they are 3 years old will be spent in a public school classroom. An individualized family service plan or an IEP is created for a student when they enter the school system. The IFSP or IEP team consists of several members whose input is critical to the development of an IFSP/IEP: parents, school personnel, and anyone else that the family feels should be a part of the team. Together, the team will decide on the least restrictive environment and the most appropriate setting for the individual with autism. For individual students, this means different settings. An appropriate education for one student may be to be included with same-aged peers in his or her home school. An appropriate education

for another student may be a self-contained classroom for children with autism within a comprehensive school. When the IEP team has come to an agreement on what is appropriate for a student, the student’s FAPE can begin.

Free Recall

Hillary Hurst

Department of Psychology, University of Massachusetts Boston, Boston, MA, USA

Definition

Free recall is a paradigm used in memory testing. It involves the presentation of information, such as a list of words or images, to the examinee, followed by a period of either immediate or delayed recall, during which the examinee is asked to produce as much of the presented information as possible. This recall can be oral or written. The primacy effect and recency effect, presented in a classic study by Murdock (1962), both affect free recall: “primacy effect” is the ability to recall information presented first more easily, and “recency effect” is the ability to recall information presented last more easily. Free recall of verbal stimuli tends to be an area of relative weakness for individuals with autism spectrum disorders because they may be less able than

individuals without ASD to make subjective connections across words that, in turn, assist with their recall (Gaigg et al. 2008). Children with ASD have been found to perform more compared to children without ASD when recall is cued or assisted, not free (Tsatsanis 2005).

Friendship Satisfaction in Children with ASD

Ayodola A. Adigun
Yale Child Study Center, New Haven, CT, USA
Albert J. Solnit Children's Center, Middletown, CT, USA

Definition

Friendship satisfaction is the overall quality that individuals perceive their relationships with friends.

Historical Background

Childhood friendship is a close connection between children based on companionship capabilities, reciprocity, and stable social interactions with a peer for greater than 6 months (Freeman and Kasari 1998). The importance of friendships was highlighted since the 1950s. Literature revealed in the 1980s that children's expectations for friendships were to improve social-emotional statuses. In addition, friendship was shown to function as a protective factor against bullying (Hodges et al. 1999). The positive effects such as enhanced self-worth, protection, and emotional growth warranted the creation of friendship scales to evaluate other possible qualifications and quantifications of relationships. For example, the Friendship Qualities Scale is a devised instrument used to assess the quality of children's and early adolescents' friendships according to five domains including companionship, conflict, help/aid, security, and closeness (Bukowski et al. 1994).

Perceived conflict in friendships was associated with higher levels of school loneliness and avoidance and lower levels of overall school engagement in boys. For both boys and girls, validation through friendships positively predicted improvements in children's school attitudes and identification of support. However, perceived exclusivity in friendships was associated with lower levels of school achievement (Ladd et al. 1996).

Companionship, intimacy-trust, and affection are distinguishable factors for friends vs. non-friends among older children during preadolescence and adolescence (Buhrmester et al. 1990). Additionally, research indicates children with secure attachments (intact trust and intimacy) with their caretakers are able to form more positive and responsive friendships compared to children with insecure parent attachments, yielding securely attached children to seek similar qualities with their companionships (Lieberman et al. 1999).

Friendship intensity, defined by the frequency that individuals saw their friends, and quality, measured by the satisfaction with friendships were found to be directly correlated to life satisfaction (Amati et al. 2018). The formation and

maintenance of friendship satisfaction is achieved through positive interpersonal and social-cognitive skills, for example, the ability to form intimate bonds and the ability to empathize (Schneider et al. 2001). The friendships of children with autism spectrum disorder (ASD) differ in quality and quantity from typical developing children due to their social-emotional limitations and deficits with their ability to understand and embrace different perspectives (e.g., theory of mind) (Bauminger et al. 2007). The logico-affective hypothesis postulates that individuals with ASD use alternative cognitive strategies to hurdle over socio-emotional difficulties that otherwise come naturally to non-autistic individuals (Bauminger et al. 2009).

Current Knowledge

Empirical evidence commonly suggests problems with reciprocal friendships with same-age peers in children with ASD. Parents' reports have also demonstrated that friendship is uncommon in children with low-functioning ASD compared to those with typical development. Conversely, high-functioning children with autism spectrum disorder (HFASD) in middle childhood and adolescence were often identified to have at least one friend, who usually was less socially impaired (Bauminger et al. 2008).

Exposure to typical peers appears to have significant effects on friendship behaviors for ASD children. Participants in mixed (ASD and typical developing peers) friendship dyads showed increased responsiveness, stronger receptive language skills, and greater positive social assimilation with closer physical proximity, communication, appropriate smiling, and eye contact and demonstrated more complex coordinated play than in the non-mixed dyads (Bauminger et al. 2007). Intellectual functioning and language abilities appear to be important potential mechanisms for supporting friendship capacities in ASD.

Studies show fewer associations have been found between loneliness and friendship for children with ASD compared to their typically developing counterparts, suggesting less understanding

of the relation between loneliness and friendship. Implications of these results are discussed for conceptualizing the social deficits in autism. Albeit having reports of having at least one friend, children with ASD may suggest poorer quality of their friendships in terms of companionship, security, and help (Bauminger and Kasari 2000; Petrina et al. 2016, 2017).

Conversely, other studies elucidate that children with HFASD and their friends perceived friendship qualities similarly, suggesting that pre-adolescents with HFASD have capacities for interpersonal awareness which positively contribute to friendship satisfaction. Current studies which examine the level of friendship satisfaction of children with ASD and their friends with and without diagnosis of ASD show relatively high levels of friendship satisfaction among all groups without significant differences (Bauminger et al. 2008).

Research has shown that friendship impacts the overall experience of mainstream school for autistic children. Furthermore, autistic children's social motivation likely determines both the nature and extent of their friendships. Adults can play an active and integral role in supporting their ASD children's friendships, but this can be conflictual to the kids' wants sometimes. These findings not only underscore the need to ascertain the perspectives of young people with autism on their friendships but also for adult caretakers to be more socially and ethically considerate of the timing and quality of intervention (Calder et al. 2012).

Future Directions

Future studies embrace the potential of identifying particular differences in social-emotional functioning and friendship building capacity specifically within the ASD population. These uncoverings can yield more clarity about friendship development and maintenance by comparing children within the spectrum who form friendships with other children with ASD in comparison to children with ASD who do not have friends. Additionally, exploring the differences of the nature of friendship within the same child with ASD while playing with a friend with a disability versus

playing with a friend with typical development can provide better understanding of the factors that contribute to a satisfactory friendship for an ASD child.

The notion that typically developing peers enhance and somewhat scaffold the social development of preadolescent children with HFASD embrace the postulation that the HFASD child uses the typical peer as a role model for learning normative social behaviors. More studies are indicated to explore the quality of friendships longitudinally through adolescence and adulthood to assess to what extent the social-emotional skills of ASD are consolidated through later years.

In other studies which explore ASD and typical development peer dyads, there was less opportunity for the child with autism to take a leadership role in the activities. This dissymmetry of power in the mixed friendship dyads indicates a need for applying intervention in inclusive settings to provide opportunities for leadership building for ASD children and, consequently, expand the possibilities for these children to have more balanced options for relationship building.

Another implication for intervention is elucidated amid the findings that ASD children in mixed friendships have stronger receptive language abilities, suggesting a relationship between language ability and peer competence (Bauminger et al. 2007). This warrants the need for more approaches that target language skill building, yielding more possibilities for educational and social success and consequently friendship building.

Parents and teachers of children with ASD play an integral role in supporting and facilitating their friendships. Thus, the direction for better understanding and contribution to friendship development implores early interventions and teacher and parent training on the development of friendships in preschool children with ASD within school and community settings.

Security attachment may, in a compensatory fashion, contribute positively to the quality of friendships of children with ASD with their typically developing and fellow ASD peers amid social-cognitive difficulties. Thus, it is mandatory in the future for more resources and training opportunities that support the fostering of responsivity

and sensitivity between parents and their children with ASD with the lens of aiding in the development of clear communicative cues. Parents also can be coached to verbally mediate the social world for their HFASD children during structured play, therefore helping them develop schemas for this form of dyadic interaction which consequently provide better opportunities for friendship development and overall friendship satisfaction (Solomon et al. 2004).

Further research is needed to examine the effectiveness of various interventions for children with ASD that help them form successful friendships with their peers. In the future, program facilitators which support friendship development with ASD and typically developing dyads through interactive activities can be more beneficial by actively serving as exemplars for teaching children with ASD how to explore their peer's different perspectives during these allotted times of engagement.

In sum, friendships are indeed obtainable for children with ASD. However, there is more understanding needed about the process of establishing, developing, and consolidating peer relationships with ASD children in order to be able to more effectively provide interventions that can yield increased friendship satisfaction. The socio-emotional encumbrances that are usually experienced with these children call for the support of parents, educators, and clinicians to foster opportunities for responsivity, reciprocity, communication, and empathy. Nonetheless, more playtime with typical developing peers can also possibly serve as useful scaffolding for improving social repertoire which can contribute to more satisfactory friendship states for children with ASD.

Friendships

Nirit Bauminger-Zviely

School of Education, Bar-Illan University, Ramat-Gan, Israel

Definition

Friendship is a type of social relationship appearing throughout the life span, from early childhood to old age. It is conceptualized under the *social relationships approach* (Hinde 1976), according to which relationships are developed through continuous dyadic interactions over long periods of time with a specific partner (a minimum of 6 months to denote friendship; Howes 1996), to extract a relationship model that goes beyond the influence of each member’s characteristics (Dunn 1993). Through friendship formation, children are “meshed” with each other to create a whole that is greater than the sum of its parts, and they share the properties and histories of their mutual interaction (Dunn 1993). The essence of friendship as a relationship is a mutual liking, whereby children reciprocate an affectionate bond of emotional closeness. Having friends is cardinal to children’s well-being and protects them from depression and loneliness, since friendship provides the child with a sense of belonging and self-worth (e.g., Asher et al. 1996; Vitaro et al. 2009).

The reciprocal-dyadic and stable nature of friendship is a challenge of child development and a necessary component in the formation of fundamental pro-socio-emotional capabilities (e.g., mutual caring, companionship, empathy, mutual regulation) as well as socio-cognitive capacities (e.g., awareness and responsiveness to

another's emotions, desires, intentions, and thoughts; conflict resolution; complex information processing processes; Asher et al. 1996). Affective closeness, which is a marker of friendship, underscores the essence of friendship as an affective bond reflecting the strength of the child's attachment to the friend. In addition to mutual liking, closeness includes the sense of "specialness" to one another, manifested in verbal and nonverbal expressions of affect and caring (Bukowski et al. 1994; Howes 1996). Intimacy (i.e., making one's innermost thoughts and feelings known to a significant other) is another important dimension of friendship (Cassidy 2001). Intimacy includes the belief that friends can be relied upon to provide support and help in times of need. Intimacy is also related to the sense of stability and reciprocity in friendship and to the belief that the friendship is strong enough to overcome negative events such as quarrels (e.g., Bukowski et al. 1994). Markers of intimacy include sharing capabilities and pro-social resources such as providing help (e.g., Bukowski et al. 1994). Friendship should also serve the need for enjoyable companionship. Companionship is usually perceived as a child's ability to spend time with another child and to have fun (e.g., "playing together," "hanging out," "doing things together"; Howes 1996). Markers of companionship include children's cooperative skills during shared work or play, as well as their social conversational skills and positive affect (e.g., shared fun) (Asher et al. 1996).

In sum, friendship is characterized by stable, frequent, and interconnected affective interactions, manifested by certain classes of behavioral markers (e.g., sharing, play, and conversational skills) that facilitate the functions of companionship, intimacy, and closeness. A satisfying friendship is an interpersonal achievement that both develops and builds upon a fundamental capacity for affective relationships and social cognition.

Historical Background

In his first description of the syndrome, Kanner (1943) historically conceptualized autism as a

disorder of affective contact, "these children have come into the world with an innate inability to form the usual, biologically provided affective contact with people" (p. 250). Kanner's description of Elaine (a 7-year-old girl with ASD) supports this conceptualization:

She soon learned the names of all the children (in her school), knew the color of their eyes, the bed in which each slept, and many other details about them, but never entered into any relationship with them. . . . She has no relation to children, has never talked to them, to be friendly with them, or to play with them. She moves among them like a strange being, as one moves between the pieces of furniture of a room. (Kanner 1943, pp. 240–241).

To this day, abnormalities in interpersonal relations are considered a defining characteristic of ASD (DSM-IV-TR, 2000). Friendship is a direct reflection of the child's capacity for interpersonal relationships, and for this reason, both the formation and the understanding of friendship in children with ASD are considered a major theoretical challenge. Contemporary perceptions of the disorder identify difficulties in friendship formation based on these children's inability to experience relationship-based emotions and on their deficit in intersubjective sharing. The results of such impairments are more impersonal and superficial rather than interpersonal friendship relationships; thus, intimacy and affective closeness, according to this view, are unattainable for ASD children (e.g., Hobson 2005). Another view is provided by theorists that highlight ASD children's difficulty in understanding that other people have different thoughts, desires, and feelings than their own (i.e., the theory of mind hypothesis). Theory of mind also predicts crucial difficulties in reciprocity and empathic pro-social behaviors (e.g., comforting, caring, complimenting, listening), which are key defining characteristics of friendship (Tager-Flusberg 2001). These two views, affective and social-cognitive, have led to a general consensus that friendship constitutes a major area of difficulty for children with ASD. In light of these theoretical assumptions, it is not surprising that friendship in ASD has recently been receiving more attention, but it is still an overlooked area of

empirical investigation, despite its significance to the understanding of the social deficit in ASD.

Current Knowledge

Friendship Formation

Studies screening for the prevalence of friendship among individuals on the ASD spectrum have presented a fairly pessimistic picture, with significant percentages found to be outside of this meaningful social experience (e.g., Howlin et al. 2004; Koning and Magill-Evans 2001; Orsmond et al. 2004). For example, half of 69 adults with ASD examined were said to have no friends with whom they share activities (Howlin et al. 2004). In another study, Orsmond et al. (2004) found that of 235 adults and adolescents, 29% had at least one friendship that involved some activities outside prearranged settings and one-quarter (24%) had peer relationships only in prearranged settings. Orsmond et al. also reported a significantly higher number of friends for younger participants (adolescents rather than adults) and for individuals with less impaired social interaction skills. Similarly, in Koning and Magill-Evans' (2001) study, 44% of their adolescent participants with Asperger syndrome had one close friend. Findings based on a slightly different paradigm, examining children and adolescents' social network and social involvement, presented a similar picture, with children on the ASD spectrum more often peripheral in their classroom and forming less reciprocal friendships compared with children of typical development (e.g., Chamberlain et al. 2007; Kasari et al. 2011; Locke et al. 2010; Rotheram-Fuller et al. 2010). The difference is more dramatic in later elementary school and during adolescence (e.g., Locke et al. 2010; Rotheram-Fuller et al. 2010). Recently, studies have begun to specifically examine friendship during preschool with regard to ASD (e.g., Bauminger-Zviely and Agam-Ben-Artzi 2014; Bauminger-Zviely et al. 2014; Chang et al. 2016; Freeman et al. 2015). Information about the number of identified friends for ASD children is provided only by Chang et al. (2016). The number of friends reported by parents (42%,

$n = 13$) and teachers (54%, $n = 17$) exceeded the number of children who were identified as having friends according to observational data (20%, $n = 7$), following an adaptation of Howes' (1983) criteria (e.g., at least 50% of social initiation attempts with responses, at least one unit of joint engagement or games, and one positive affective exchange during the interaction). Nine (29%) sets of parents and teachers identified the same friends; however, parents reported friends from other settings in addition to school, such as family friends ($n = 13$), outside activities ($n = 6$), and the neighborhood ($n = 6$). Further examination of the number of friends for ASD children in preschool is still needed to clarify the gap between parents/teachers and observational reports. Also Bauminger-Zviely and Agam-Ben-Artzi (2014) identified 30 high-functioning preschoolers with ASD who enjoyed at least one reciprocal friendship, based on mother's and teacher's reports and verified by an observation in the child's preschool.

Other studies focusing specifically on friendship in HFASD (high-functioning ASD) have demonstrated the presence of at least one reciprocal friendship in these children (e.g., Bauminger and Kasari 2000; Bauminger and Shulman 2003; Bauminger et al. 2008b; Daniel and Billingsley 2010). Based on these different findings, we may conclude that friendship, though not frequent, is an attainable experience at least for certain subgroups of ASD children, probably for those with higher cognitive and language skills. The two periods with somewhat higher percentages of friendship are middle childhood and early adolescence, with adults showing less frequent experiences of friendship (e.g., Mazurek 2014) and with as-yet unclear numbers regarding young children with ASD.

Very few studies evaluated the characteristics of children who make friends. Chang et al. (2016) have examined spontaneous peer interactions and play compared preschoolers with friends to preschoolers who do not have friends. Children with friends were more likely than children without friends to be jointly engaged with their peers during free play and used higher joint attention skills. In line with these findings, Freeman et al. (2015) examined the influence of joint attention

and play on the quality of friendship among 40 children as measured 5 years later via parent and child reports. The authors found that children who had better joint attention skills at the age of three reported having more closeness and less conflict in their friendships at the age of eight. Children who had better play abilities in general, and specifically greater variability and flexibility in symbolic play, conveyed higher levels of helpfulness in their friendships. These are important results that link core deficits to later friendship development in ASD.

Friendship characteristics. Variables of friendship such as the friend's attributes (age, gender, type of disability), the duration of the friendship, and the frequency of play dates have rarely been explored in children with ASD. Based on the few findings presented in the literature (e.g., Bauminger-Zviely and Agam-Ben-Artzi 2014; Bauminger and Shulman 2003; Bauminger et al. 2008b; Howlin et al. 2004; Kasari et al. 2011; Orsmond et al. 2004; Locke et al. 2010; Petrina et al. 2015), we may conclude with caution that both mixed and nonmixed friendships (i.e., friendship with a child of typical development and friendship with a child with a disability, most likely ASD, respectively) have been found in children with ASD, although the percentages of children who form each type of friendship are not yet clear.

Petrina et al. (2015) assessed school-age friendships with regard to reciprocity and mutuality included 37 boys and 8 girls between the ages of 6.4 and 10.4 years (mean, 8.5; SD, 0.9). Forty-nine percent ($n = 22$) of the ASD group were in a nonmixed friendship dyad, and 51% ($n = 23$) were in a mixed friendship dyad. The level of friendship quality was assessed by the Friendship Quality Questionnaire (FQQ; Parker and Asher 1993), and both friends from each dyad answered the questionnaire using a three-point response scale. According to the answers, the friendships were classified as a best, regular, or nonfriendship. The results showed that 89% of the friendships (i.e., 42 out of 47) across both mixed and nonmixed dyads were reciprocated. The reciprocation rate was 19% for best friends, 15% in the mixed dyads and 24% in the nonmixed, and 55% for

regular friendship, 54% in the mixed dyad and 62% in the nonmixed dyad. The majority of friendships consist of same-age and same-gender couples. Surprisingly, the duration of the friendship was found to be relatively long, ranging from about 1–4 years, but the frequency of play dates outside the school was reported to be about once a week, which is lower than for typically developing children. As mentioned, these somewhat optimistic findings should be further examined, especially with regard to the quality of the relationship. In a meta-analytic study that examined the friendships of school-aged boys with ASD Mendelson et al. (2016) found that boys with ASD do form reciprocal friendships in which they engage in affective sharing, although it is of lower quality. In typical development, friendship functions as an important source of emotional support and as a marker for social adjustment, but the consequences of friendship for children's psychosocial development are highly dependent on its quality (e.g., Vitaro et al. 2009).

Friendship quality and associated behaviors. The quality of the friendship relationship is probably the most debated topic in ASD. Even if researchers agree that some children with ASD do have friends, they will still question the quality of this relationship. More specifically, difficulties in experiencing intimacy and closeness are expected in these children. One source of information on the quality of friendship is children and adolescents' self-reports. Several studies have used Bukowski et al.'s (1994) Friendship Qualities Scale (FQS), which assesses children's reports about their relationship with a close friend in the following dimensions: companionship, intimacy-security, closeness, help, and conflict (e.g., Bauminger and Kasari 2000; Bauminger et al. 2004; Bauminger et al. 2008b; Chamberlain et al. 2007; Kasari et al. 2011; Locke et al. 2010). In these studies, the friendship quality in ASD children was found to be poorer compared with friendship in children of typical development, especially for intimacy, help, and companionship (e.g., Bauminger and Kasari 2000; Bauminger et al. 2004, 2008b; Chamberlain et al. 2007). Differences on the dimension of closeness between the two groups were reported

by Bauminger et al. (2008b) (preadolescence, age range 8.6–12.6) and Kasari et al. (2011) (middle childhood, age range 6–11). Interestingly, the FQS did not show friendships of children with ASD to be more conflictual than those of typically developing children.

In another study, this time examining adults, Baron-Cohen and Wheelwright (2003) provided support for lower friendship quality, revealing less close, empathic, and supportive friendships, in adults with ASD compared with typical controls. Jobe and Williams-White (2007) obtained similar results for adults with severer autism symptoms. Altogether, self-reported friendship quality of HFASD children and adults portrayed difficulties in the formation of quality friendship with peers. This finding has clinical significance: it is interesting that individual with such limited interpersonal awareness and knowledge (e.g., Carrington et al. 2003; Hobson 2005) can reveal a realistic picture of the quality of their friendship, implying that they are aware of their difficulties in interpersonal engagement. In Daniel and Billingsley's (2010) study, 10- to 14-year-old boys described the establishment of friendship as the most difficult aspect in their social life. Higher ratings of loneliness were found in children with HFASD compared with typically developing children (e.g., Bauminger and Kasari 2000; Locke et al. 2010), a finding which may also support the finding of children's awareness of their social difficulties in forming relationships. Such awareness has significant clinical implications, especially in light of accumulating evidence showing high rates of affective disorders (65%; Attwood 2004) such as anxiety, depression, and social isolation, in high-functioning ASD adolescents and adults compared with typical controls (e.g., Attwood 2004). Lack of friends may be one of the reasons for the increase in affective disorders during adolescence and adulthood.

Further support for the notion of lower friendship quality in children with ASD has been provided by observations on children's social interactions with a friend (e.g., Bauminger et al. 2008b) and comparisons between interactions with friends and nonfriends (Bauminger-Zviely and Agam-Ben-Artzi 2014). In Bauminger

et al.'s study, HFASD and typical children's social interactions and their dyadic qualities were coded during an encounter with a friend in two different, noncompetitive play activities: building with blocks and drawing. Results demonstrated significant differences between the two groups in cooperative skills and positive affect on both the building and the drawing activities; differences in sharing were found only in building, and differences in nonverbal behavior were found only while drawing. The play scale, coded only for the building activity, showed a lower frequency of coordinated play and higher frequency of parallel play in the HFASD group than in the typical group. Pairs in which at least one child had HFASD also differed in conversational flow and social conversation. The HFASD group revealed a more rigid conversational style and engaged in less social conversation compared with the typical children. Group differences emerged in all dimensions of the dyadic relationship Q-set that evaluate dyadic quality of interaction between friends (Park and Waters 1989) (positive social orientation, cohesiveness, harmony, responsiveness, coordinated play, and control), except control, with HFASD pairs demonstrating poorer dyadic quality of friendship than typical pairs. A global evaluation of affective closeness and shared fun found that friendships between children with HFASD were lower on these two dimensions compared with typical friendships. It is important to note that children with higher receptive language abilities enjoyed better friendship quality.

Thus, it is safe to conclude that the quality of friendships among children with HFASD is poorer than among typical children. The picture is not complete, however, until a comparison is made between HFASD children's interactions with friends and with nonfriends, for only such a comparison can demonstrate the differential role of a friend to the enhancement of these children's social capabilities. In a recent study (Bauminger-Zviely and Agam-Ben-Artzi 2014), the author and colleagues explored friendship in preschoolers with HFASD. Each child was videotaped interacting with a friend and with a nonfriend while building with blocks, drawing, and during snack time. Results indicated that HFASD

children showed more positive affect and higher degrees of closeness, shared fun, and reciprocity when interacting with a friend compared with a nonfriend. Furthermore, pragmatic skills such as reciprocal conversation, responsiveness to the interlocutor, co-regulation of the conversation, appropriate reference to the other's emotions, appropriate use of facial expressions and eye contact were more intact during interactions with friends versus nonfriends (Bauminger-Zviely et al. 2014), as well as greater conversational adequacy, more initiations of conversational exchanges, and more responsiveness to information evoked by the partner during interaction with friends versus nonfriends dyads (Bauminger-Zviely and Agam-Ben-Artzi 2014). Bauminger-Zviely et al. (2017) showed better use of speech acts-SA (SAs; the primary illocutionary values conventionally conveyed by utterances as acts), during interaction with a friend versus a non-friend. Thus, friendship may serve an important function in the enhancement of social-communicative skills in HFASD.

To complete the discussion on friendship quality, it is important to discuss the partner's contribution to the friendship, namely, whether differences can be found between mixed and non-mixed friendships. In Bauminger et al. (2008a), the author and colleagues examined differences between mixed (HFASD and typical child), nonmixed (HFASD and child with disability, mainly with HFASD), and typical friendships (both children typical). Findings showed that mixed dyads were similar to typical friendship dyads in many of the observational measures collected. More specifically, mixed typical and HFASD dyads differed significantly from non-mixed dyads but not from typical dyads in the amount of engagement in goal-directed activity, sharing, positive affect, and parallel play. Mixed dyads were found to be more responsive and cohesive and to be higher in positive social orientation and to show more complex levels of play (coordinated play), compared with nonmixed dyads. This finding points to the possible benefits to the HFASD child of having a typical child as a friend. Further, according to this study, HFASD children in mixed friendships differed from

HFASD children in nonmixed friendships only in receptive language, demonstrating higher language skills. Other differences were not significant: HFASD children in both friendship types (mixed and nonmixed) showed high social-emotional characteristics including theory of mind (ToM), affective recognition, and attachment to parents.

On the other hand, an important advantage of nonmixed friendship (i.e., friendship between two disabled children) was the element of equality in the exchange: children in such dyads maintained a balance in the degree to which each partner assumed dominant or subordinate roles such as leader and follower, whereas children in mixed friendships had fewer leadership opportunities. Thus, it appears that interactions with a similarly disabled friend (most likely another child with HFASD) are also very important. Based on the studies described, a complete understanding of friendship quality in HFASD requires consideration of the characteristics of the friend, with seeming benefits from participation in both mixed and nonmixed friendships. Further studies should investigate the different benefits of participation in each of the friendship types for the child with HFASD.

Understanding of Friendship

Although interpersonal awareness and understanding are considered to be severely deficient in ASD (Hobson 2005), few studies have focused on ASD children's ability to understand the concept of friendship. One example is Carrington et al. (2003) study, which examined descriptions obtained through semi-structured interviews with five adolescents with Asperger syndrome aged 14–18, of what a friend is, as well as what a friend is not. The adolescents demonstrated difficulties explaining what a friend is: explanations were usually superficial and focused on sharing activities (e.g., computer games such as *Dungeons and Dragons*) and other areas of interest, without mentioning more emotional aspects of friendship, such as liking each other. Bauminger et al. (2004) provided additional support for these children's major difficulties in capturing the more affective dimensions of friendship. In their study, children

(8–17 years) were shown a picture depicting two children in an intimate exchange, looking at each other, smiling, and appearing to be telling each other a secret. Participants were asked to suggest a title and make up a story to go with the picture and to say whether the children in the picture were friends. Only 50% of the HFASD compared to 81.3% of the typical control group named the picture in a way that referred to friendship. Among those who did, only one child with autism referred to the intersubjective sharing and closeness aspect of the friendship (the child suggested the title “soul mates”), compared with many of the typical children (e.g., “best friends,” “secret friends,” “brotherhood”). In Bauminger and Kasari (2000), HFASD children showed difficulty in all three defining aspects of friendship, namely, closeness, companionship, and intimacy. In sum, it is clear that the pragmatic understanding of friendship is lacking in these children, as well as the use of language to describe it. However, it is important to emphasize that lack of understanding may not necessarily preclude the experience of friendship. These children may have specific difficulties in reflecting about their interpersonal experience.

Future Directions

There is little doubt that ASD is a disorder involving severe deficits both in experiencing and understanding friendship. However, friendship is not an all-or-nothing concept, and for these children, some of whom do have friends and whose friendships are of great importance to them, even more limited forms of friendship can be fairly durable. Although consistent difficulties have been demonstrated across studies examining the understanding and experience of friendship in ASD, a subgroup of ASD children has nevertheless emerged, who show higher interpersonal awareness and a better quality of friendship. The phenomenon of friendship in children with ASD would probably best be described as a continuum of interpersonal resources, with some children able to develop relationships or even meaningful and enduring friendships, others capable of more superficial attachments in which the friend is

merely a playmate rather than an intimate “soul mate,” and still others being unable to develop any type of stable relationship with a friend or even having not yet developed the desire to have a peer as a friend. This continuum should be further explored in order to identify what characterizes each of these subgroups, and such exploration is indeed under way in the field of typical friendship research, which is beginning to examine various types and functions of friendships (see, e.g., Kerns 2000, for preschool friendship, and Shulman 1993, for adolescents).

Just as the child with ASD clearly plays a significant role in determining the quality of the friendship, so does the friend, with typically developing friends probably helping to promote more complex interactions, and friends with a disability contributing more to aspects of equality in the friendship. Language skills have also been found important, with children of higher language skill appearing to develop higher quality friendships. In this respect, it is important to note that children with ASD in both mixed and nonmixed friendships reveal high social-emotional abilities such as ToM, security of attachment, and affective recognition. Perhaps, within the spectrum of ASD, these children with higher social, cognitive, and emotional resources do develop friendship. What helps children develop a friendship with a typical peer, beyond better language skills, has yet to be explored.

Another reason why friendship is an uncommon experience in ASD may be because social interventions tend to neglect focusing on friendship. Theoretical assumptions of friendship as a nontangible experience for children within the spectrum may limit professionals’ attempts to discover ways to support, encourage, and build up ASD children’s ability to form friendships when planning social interventions. Only rarely is friendship a target of such interventions for this population, and very few social intervention programs (specifically at younger ages) are aimed at developing and maintaining friendships (e.g., Frankel and Myat 2003). In adolescence, for example, children with ASD consistently perceive themselves as lonelier than typically developing children (e.g., Bauminger and Kasari 2000). For these reasons, friendship should be considered an aim of ASD social intervention across the

lifespan, and future studies need to further explore the necessary skills leading to the formation of friendship in ASD. Friendship in young children particularly merits thorough investigation due to its preventive value. Another important direction for research is the identification of early markers of higher interpersonal resources and capacities for richer friendships in children within the ASD spectrum. Also, since friendship has not been carefully explored in children with lower cognitive and language skills and little is known about these children's ability to form friendship, further research is warranted. Companionship skills seem to be easier to teach, but the real struggle is helping these children share their innermost feelings and thoughts and develop intimacy and affective closeness with a friend. To conclude, we are presently at the most initial stages of untangling the intricacies of interpersonal engagement with friends in ASD. Longitudinal studies exploring the phenomenon are needed, alongside the planning of interventional goals to enhance friendship in children with ASD.

Structure

Frontal Lobes: Anatomy and Function

The frontal lobes constitute the largest part of the human brain. Anatomically, they represent those areas of the cortex anterior to the central sulcus. They are the last to mature during development, and only reach full maturity by the mid-20s.

Function

The frontal cortex can roughly be divided into the following parts with corresponding functions:

- *Frontal operculum*: language, mirror mechanisms
- *Precentral*: motor
- *Dorsolateral prefrontal*: executive functions
- *Orbitofrontal/ventromedial*: emotion, decision-making, response inhibition
- *Anterior cingulate*: choice selection, reward, social emotion, empathy, response monitoring
- *Medial prefrontal*: social cognition

Lesions of the frontal lobes are characterized by profound personality changes, described in the famous case of Phineas Gage (Damasio 1994). Other elements of frontal dysfunction may include perseveration, aphasia, lack of spontaneous activity, indifference, or disinhibition. Some of the effects resulting from frontal lesions are due to the fact that the orbitofrontal cortex is extensively connected to the amygdala and subcortical structures and can be considered as one of the elements of the limbic system.

In order to tap into their different functions, including language production, motor, and executive functions, neuropsychological testing of frontal lobes is performed with a variety of tasks. A vast number of tests are available to test language production, including the Boston Naming Test. Neurological examinations are used to test for motor functions. Executive functions (EF) include skills required for action planning and execution, inhibition, organization, self-monitoring, cognitive flexibility, and set-shifting. EF tests include Go/No-Go task, Trail Making

Test (TMT), Lexical Fluency, attention and concentration tests (e.g., serial 7), digit span, alternative sequence task, Tower of Hanoi (or of London), and Wisconsin Card Sorting Test (WCST). In addition, a computerized battery for testing EF is available: the Cambridge Neuropsychological Test Automated Battery (CANTAB) (Robbins et al. 1994).

Below, we describe the findings of neuropsychological, anatomical, and functional studies in ASD.

Pathophysiology

Neuropsychological Studies

Executive functions: Abnormalities in executive functions are very common in autism, although their relationship with autistic symptomatology is complex (Joseph and Tager-Flusberg 2004; Kenworthy et al. 2008). In their review, Kenworthy et al. (2008) note that while there is a consensus about difficulties in various aspects of executive functions in daily life of individuals with autism, a number of questions remain in terms of their performance during neuropsychological testing. In particular, this review underlines the fact that while abnormal performance has been observed in tasks that required human administration and hence adherence to socially presented rules and interactions (such as the WCST or the Tower tasks), less impairments are reported in ASD when tests are administered using CANTAB, a computerized battery. A more recent review (Demetriou et al. 2019) suggests that the heterogeneity of EF difficulties needs to be quantified and that a RDoC approach may be needed to better understand potential ASD subtypes based on EF functions.

Other confounding factors in EF studies in ASD are IQ levels and age, with differential maturation trajectories of components of EF during adolescence. A robust finding, however, is the presence of spatial working-memory deficits. Ecologically valid EF control questionnaires (e.g., BRIEF) reveal that both children and adults with ASD have difficulties on unstructured tasks, but the potential confound with social demands on these measures still need to be better understood.

Mirror mechanisms: Mirror mechanisms were first described in primates and rapidly thereafter in humans by the group of Giacomo Rizzolatti (Gallese et al. 1996; Rizzolatti et al. 1996). The caudal part of the inferior frontal gyrus (corresponding to Broca's area on the left hemisphere) is part of the action mirror network. Mirror mechanisms translate sensory information during observation of an action done by others into that same action coded in the observer's motor system. The result of this sensory-motor transformation depends on the location of the mirror neurons: for neurons in the motor system, mirror mechanisms will make possible the understanding of action and imitation; for neurons located in the insula and the cingulate, mirror mechanisms will support emotional understanding and empathy. Language is very likely to have evolved from mirror mechanisms (Rizzolatti and Arbib 1998).

The results of studies addressing imitation deficits in autism are sometimes contradictory (for review, see Seveler and Gillis (2010)), probably partly due to the fact that the term "imitation" covers several categories of behaviors, including emulation, mimicry, and true imitation, and that imitation tasks used in different studies are extremely variable.

Imitation performance in ASD depends on task type (Rogers et al. 2003). Children with autism seem to be capable of elicited imitation, but do not show a tendency to spontaneously imitate (Ingersoll 2008; Whiten and Brown 1999; but see Bird et al. 2007). One common finding in ASD is the lack of automatic mimicry and spontaneous imitation of facial expressions (reviewed in Seveler and Gillis (2010)). The EP-M model (emulation and planning-mimicry; Hamilton 2008) suggests that while the EP route is intact, the M route, responsible for automatic mimicry and spontaneous imitation, may be impaired in children with ASD.

Training of motor imitation can reduce other symptoms (e.g., improve language) in ASD (Ingersoll and Lalonde 2010), and neurofeedback training during imitation and observation seem to result in behavioral improvement in ASD (Datko et al. 2018).

Joint attention (JA), theory-of-mind (ToM): Deficits in joint attention are one of the first symptoms to appear autism (for review, see Mundy (2003)). Capacity for joint attention normally emerges at 6 months of age and is a prerequisite for social learning. ToM is the capacity to attribute mental states to oneself and others, and deficits in ToM have been a prevalent theory in autism (Baron-Cohen et al. 1985). However, a fair amount of empirical evidence seems to fail supporting the claim of an impairment of ToM in autism, as recently reviewed in Gernsbacher and Yergeau (2019), who show that tasks used in the past to evaluate ToM failed to account for autistic traits, social interaction, and empathy. In particular, it appears that many tasks rely on language comprehension (e.g., False Belief task, Strange Stories task, Reading-the-Mind-in-the-Eye task); therefore, it is not a surprise that autistic individuals with communication impairments would perform less well in these tasks.

Anatomical Studies

Brain Volume and Cortical Thickness

Anatomical differences in ASD brain are reviewed in Amaral, Schumann, and Nordahl (Amaral et al. 2008). A common theory posits that ASD brains undergo a period of precocious growth during early postnatal life, followed by a deceleration (for review, see Courchesne et al. (2004)) related to a disproportionate increase in white matter (Herbert et al. 2003). Greatest increases in volume have been observed in the dorsolateral prefrontal and medial frontal cortices (Carper et al. 2002; Herbert et al. 2004), whereas no differences have been reported in the orbitofrontal cortex. A longitudinal study reports that by age 2.5, both cerebral gray and white matter are significantly enlarged in toddlers with ASD, with the most severe enlargement occurring in frontal, temporal, and cingulate cortices (Schumann et al. 2010). Abnormalities in gyrification of the inferior frontal gyrus, as well as cortical thickness decreases in the inferior frontal cortex, have been described (Ecker et al. 2010; Hadjikhani et al. 2006). In the dorsolateral

prefrontal cortex, Casanova et al. have observed abnormal minicolumns (Casanova et al. 2002). A more recent microstructural study has revealed focal patches of abnormal laminar cytoarchitecture and cortical disorganization in the prefrontal cortex of children with autism (Stoner et al. 2014).

Diffusion Tensor Imaging (DTI) Studies

Multiple studies have described white matter alteration in the frontal lobes in ASD. Most DTI studies report reduced fractional anisotropy (FA) in frontal white matter in adolescents and adults with ASD (Alexander et al. 2007; Barnea-Goraly et al. 2004; Keller et al. 2007; Thakkar et al. 2008) as well as in children (Kumar et al. 2010; Sundaram et al. 2008).

Opposite findings (increased FA in the frontal lobe) are reported in children, suggesting the role of a developmental component, with an early and accelerated abnormal maturation of the white matter (Ben Bashat et al. 2007). Increased myelination of the frontal lobe was also described in a study using T2-weighted imaging in young children with ASD (Carmody and Lewis 2010).

Because ASD most probably is the consequence of several possible pre-, peri- and postnatal pathogenic events that affect neural proliferation and migration (see above) as well as myelination, pruning, axonal development, and connectivity, it is to be expected that differences will be present in the white matter. A recent review nicely illustrates all the findings related to structural neuroimaging in ASD (Girault and Piven 2020).

Functional Imaging

Activation Studies

Activation studies have addressed different functions of the frontal lobes.

Language: Semantic processing is associated with stronger activation in Broca's area in adolescents with ASD, who also exhibit less laterality for this area (in the context of similar behavioral performance) (Knaus et al. 2008). In adults, other studies have shown reduced activation in Broca's

area during semantic processing; however, behavioral performance was not equal between groups, making the interpretation of the data difficult. A recent meta-analysis of 22 published studies (Herringshaw et al. 2016) reported increased left middle frontal and right inferior frontal gyrus activity in ASD during language processing, in particular in tasks with poorer performance accuracy for the right IFG.

Motor functions: Very few functional studies have examined the imaging correlates of motor dysfunctions in autism. Mostofsky et al. (2009) describe greater activation of the supplementary motor area (SMA) during finger tapping task in children with autism, compared to controls who tend to engage the cerebellum for this type of task. In addition, a recent study has demonstrated atypical lateralization in circuits subserving motor functions (Floris et al. 2016).

Executive functions: Four main caveats need to be underlined in functional imaging of EF in ASD. The first critical issue is the necessity to compare brain activation in tasks where behavioral performance is similar between the groups being compared. A second issue is that the fact that age may play a role in the synchronization of frontal and fronto-striatal brain regions involved in response inhibition and that in consequence age groups need to be strictly defined and homogeneous. A fourth issue is the very common comorbidity of ADHD and ASD, which would be de facto associated with EF difficulties. Finally, one has to bear in mind that an abnormal developmental trajectory may also be the basis of the differences observed in children and adolescents with ASD.

The majority of functional magnetic resonance imaging (fMRI) studies of EF in ASD have demonstrated diminished brain activation compared to controls, with some exceptions (reviewed in Solomon et al. (2009)).

Mirror mechanisms: Several functional studies using different imaging techniques including fMRI, electroencephalography (EEG), and magnetoencephalography (MEG) have reported abnormalities in mirror mechanisms in ASD. In neurotypicals, action observation is typically associated with a suppression of the mu rhythm in the EEG signal – a phenomenon that seems

absent in ASD (Oberman et al. 2008). Using transcranial magnetic stimulation (TMS), Theoret et al. (2005) have demonstrated that TMS applied over the primary motor cortex did not modulate the excitability of the primary motor cortex in children with ASD, contrary to controls.

fMRI studies in children and in adults have reported weaker activation of the frontal operculum during face or body emotion expression perception (Dapretto et al. 2006; Hadjikhani et al. 2007; Hadjikhani et al. 2009).

However, recent studies report normal (Dinstein et al. 2010) or even enhanced (Martineau et al. 2010) activation of mirror system areas during action observation, or during perception of facial expression of pain (Hadjikhani et al. 2014), leaving the question of atypical activity of the MNS in autism open.

Reward processing: One of the current hypotheses about social impairments in autism is a lack of social motivation, due to a decreased reward value for social stimuli. A recent systematic review and meta-analysis (Clements et al. 2018), including 30 studies, points to hypoactivation of the anterior cingulate in ASD during social rewards, nonsocial rewards, and restricted interests.

Social emotion, joint attention: Normal activation has been reported in middle prefrontal cortex during social-emotional tasks (Schulte-Ruther et al. 2010). However, hypoactivation has been observed during tasks of joint attention (Zürcher et al. 2013; Oberwelland et al. 2017).

Response monitoring: Abnormal (increased) anterior cingulate activation has been shown in response to correct trials during response monitoring in ASD (Thakkar et al. 2008).

In summary, functional activation studies remain controversial, and a better understanding of frontal functions in autism will require further investigation.

Functional Connectivity Studies

A common finding of functional connectivity studies has been the presence of underconnectivity in ASD between large-scale networks and over-connectivity in small-scale

networks. In most studies specifically addressing connectivity of the motor system (Mostofsky et al. 2009) and of the EF system (Just et al. 2004; Kana et al. 2007; Koshino et al. 2005; Solomon et al. 2009; Thakkar et al. 2008), underconnectivity was reported. However, other groups show no differences (Lee et al. 2009) or even increased (Shih et al. 2010) connectivity in the frontal regions in ASD (superior frontal and anterior cingulate) – concluding to atypical connectivity of the imitation network with an enhanced role of the dorsal prefrontal cortex. The different findings of resting-state functional connectivity in autism have recently been reviewed by Hull et al. (Hull et al. 2016).

One major caveat needs to be kept in mind for functional connectivity studies: we know that that slightly different motion magnitudes may induce spurious differences between groups, and this factor needs to be specifically addressed in studies (Van Dijk et al. 2012).

Perspectives

Because of the developmental trajectory of executive functions and of the frontal lobes in general, future studies will need to have larger number of participants, with homogeneous age groups and cognitive abilities (IQ). In addition, functional studies will need to be designed so that behavioral performance is equal between groups, if brain activations need to be compared for a specific task.

Disorder of executive dysfunction; Dysexecutive syndrome; Frontostriatal disorder

Short Description or Definition

The frontal lobes are the slowest regions of the central nervous system to fully develop, rendering them more susceptible to neurodevelopmental disorders, such as autism spectrum disorder, than any other region (Bradshaw 2001). The frontal lobes form part of key brain regulatory circuitry where multiple cortico-striato-thalamo-cortical loops connect the frontal lobes to the rest of the brain. Frontal lobe syndromes have in common abnormalities in structure and chemical balance in the frontal lobes, basal ganglia, and thalamus. Abnormalities in these structures and chemical imbalances are proposed to lead to deficiencies in the domains of cognition, emotions, and motor control. A mixture of these deficiencies can explain the symptomatology observed in classic frontal syndromes of childhood, for example, autism, Asperger's disorder (henceforth to be referred to as "autism spectrum disorder"), and attention deficit hyperactivity disorder (ADHD), and neurodegenerative frontal disorders, for example, Parkinson's and Huntington's disease. The common basis accounts for why there is high comorbidity within neurodevelopmental and neurodegenerative sub-groupings of frontal syndromes; for example, it is common for children with autism to also have clinical manifestations of ADHD. Such comorbidity may also point to common heritability factors across syndromes.

Categorization

Disorders which arise from damage to the frontal lobes are often referred to under the umbrella term of "frontal lobe syndrome." Frontal lobe syndrome can result as the consequence of: (1) developmental problems with the frontal lobe, as is the case with autism spectrum disorder, ADHD, obsessive compulsive disorder (OCD), Tourette's disorder (TD) schizophrenia, and depression, (2) degeneration of the frontal lobes, for example, Parkinson's disease, Alzheimer's disease, and Huntington's disease, or (3) Acquired brain injury, for example, stroke or traumatic brain injury.

While autism is defined in DSM-IV-TR (American Psychiatric Association 2000) as a psychiatric disorder, it is commonly referred to as a disorder which crosses the psychiatry-neurology divide, involving both “psychiatric” and “neurological” symptoms. When we consider autism under the umbrella of a “frontal lobe syndrome,” we group autism with other disorders where vital brain pathways which connect the frontal lobes to the rest of the brain are disrupted, either through genetic abnormalities, or environmental insult. While some of these disorders fall within the categorization of “neurological” disorders, for example, Parkinson’s disease, others fall under the categorization of psychiatric disorders, for example, autism and ADHD. It has been argued that the division between neurology and psychiatry is in many ways arbitrary; in the case of autism, frontal-related symptoms such as “repetitive motor mannerisms” could be considered as a neurological “motor disorder” or as a psychiatric “perseverative” phenomenon.

The question remains whether the presence of a particular frontal lobe syndrome is a necessary precursor for the development of autism and AD, given that some autistic behaviors (e.g., stereotyped or ritualistic activities) are present in other childhood psychiatric disorders, such as TD, OCD, and ADHD. It may be considered that autism, TS, OCD, and ADHD are five clusters of behaviors that represent disorders in several discrete dimensions, such as communication, social skills, or stereotyped/ritualistic/obsessive behavior. Autism and AD may be thought of as occurring at the same end of the social ability continuum, but as occurring at different ends of the communication ability continuum, while OCD and TS may lie toward the less-impaired ends of these dimensions. Alternatively, on the stereotyped movements-obsessive behaviors dimension, autism and TS may be thought of as occurring at the “stereotyped movement” end of the continuum, with OCD occurring at the “obsessive behaviors” end. These diagnostically distinct disorders may simply reflect different combinations of a finite set of behavioral disturbances (Bradshaw 2001).

Epidemiology

ASDs are highly prevalent with the incidence estimated at between 60 and 90 per 10,000 individuals (Autism and Developmental Disabilities Monitoring Network Surveillance Year, Principal Investigators, Centers for Disease Control and Prevention 2009; Fombonne 2009), although a recent study of students aged between 5 and 9 years in the United Kingdom sets this estimate to approximately 160 in 10,000 (Baron-Cohen et al. 2009). It is likely that the apparent increase in prevalence is due to better diagnosis and awareness in the general public. The apparent “epidemic” of ASD is similar to the increased ascertainment of ADHD in the 1990s. For this reason, “ASD” is sometimes referred to in the context of being the “new ADHD.”

Although the precise cause of executive dysfunction in ASD is not known, researchers have used neuroimaging and electrophysiological techniques to demonstrate atypical activation across a range of frontostriatal cortical and subcortical structures. This includes, for example, hypoactivation of inferior frontal gyrus, orbitofrontal cortex, and ventral medial prefrontal cortex, and hyperactivation of supplementary motor area, dorsal anterior cingulate, and middle frontal gyrus. This is presumably underpinned by various neurochemical abnormalities that have demonstrated relevance to both executive function and ASD, including abnormal serotonergic, dopaminergic, glutamatergic, and GABAergic function. More recent evidence also points to the role of impaired neural connectivity within frontostriatal circuitry, which includes reduced integrity of white matter pathways. There are, however, no consistent results in ASD demonstrating structural abnormalities (e.g., lesions) that reflect what is typically seen in frontal lobe syndrome (FLS) associated with acquired or neurodegenerative presentations.

Natural History, Prognostic Factors, Outcomes

While autism manifests in the first 3 years of life, the full extent of the disorder unfolds as the slowly

developing frontal lobes reach maturity; this in part contributes to the changing clinical manifestation of autism throughout childhood and adolescence (see “Clinical Presentation” below).

The term most commonly used to describe the impairments which arise from disruption to the frontal lobes is “executive dysfunction.” Executive dysfunction can be thought of as a loss or disruption to skills which we require to interact in a flexible way with the environment, solve problems, plan, engage efficiently in goal-directed behavior, and defer or inhibit responses. Overall, frontal lobe syndrome results in a deficit in maintaining appropriate problem-solving set for the attainment of future goals (Bradshaw 2001).

Pennington et al. (1997) proposed the “executive dysfunction hypothesis” of autism spectrum disorder on the basis that there is severe, early disruption to the frontal areas, disrupting the ability to plan complex behaviors. Working memory deficits are also noted as being important to this theory. Poor performance on tests of executive functioning is common in children with autism.

Neuropsychological research has shown that two core aspects of frontal lobe function are disturbed in autism: (1) reduced cognitive flexibility, which refers to the ability to shift one’s focus of attention from one feature, or cognitive set, to another and (2) perseveration, which refers to a tendency to repeat a verbal or nonverbal behavior beyond what is required. These frontal syndrome deficits underpin the daily challenges a child with autism experiences with planning and organizing tasks required for everyday life. The ability to sustain attention and inhibit responses has been shown to be generally intact in individuals with autism using standardized neuropsychological tests (see “Evaluation and Differential Diagnosis” below). Using more novel experimental paradigms, there is some evidence to suggest that one aspect of inhibitory function may be impaired in autism, verbal inhibition (see Rinehart et al. 2006). Such deficits are also seen in patients with neurodegenerative “frontal lobe” syndrome, Parkinson’s and Alzheimer’s disease, and neurodevelopmental disorders such as schizophrenia.

The difficulties an individual with autism has with cognitive flexibility persist into adult life. In

contrast to children with autism, adults with autism can develop better skills for managing executive dysfunction, either through further acquirement and practice of techniques to scaffold executive difficulties (see “Treatment” below), via greater insight into their own inflexibility, or through greater desire to follow the rules and behaviors necessary for successful adult life.

There is some evidence that children with autism experience a “second wave” of executive deficits around puberty due to a divergence in the developmental trajectory of the frontal lobes (Minshew and Williams 2007). At around this time children with autism are also likely to suffer from depression; this may manifest as mood disturbance and irritability, sleep and appetite disturbance, and thoughts of suicide (Tonge and Rinehart 2006). Organizational and planning deficits can become more pronounced when children are depressed or anxious. In addition to pubertal brain development, particularly impacting on the frontal lobes, the increased vulnerability to depression during adolescence may be associated with increased insight into the disorder. Graduation from Primary School, or other change in educational placement, which tends to coincide with puberty, is often a major stress for children with autism. When individuals with autism exhibit self-injury and aggression, in addition to executive dysfunction, as often occurs with individuals who have associated intellectual disability, this can result in socially inappropriate and “disinhibited” behavioral patterns which can reduce successful participation in the school and community settings, and may require more restricted care plans.

Comorbidity with other neurodevelopmental disorders, which fall under the umbrella term of “frontal lobe syndromes,” may also impact on quality of life. This comorbidity may be genetically determined, as is likely the case with ADHD, a stress-induced vulnerability, or both, as is the case for Tourette’s disorder. For example, clinically significant symptoms consistent with ADHD are reported to be highly prevalent in children with autism spectrum disorder. (Note that despite this overlap in diagnostic symptoms, our major diagnostic classification system

(DSM-IV-TR) currently precludes a dual-diagnosis of autism and ADHD.). There is some empirical evidence that children who present with autism and clinically significant levels of ADHD have higher levels of emotional-behavioral disturbances (Gargaro et al. 2010). In the case of Tourette's disorder, a frontal syndrome vulnerability, together with environmental stress, possibly related to biological or situational changes (see above), may trigger the comorbid presentation of Tic disorder or full-blown Tourette's disorder.

Clinical Expression and Pathophysiology

Executive dysfunction, in part, gives way to one of the most striking paradoxes of autism, the contrasting and uneven development of skills, sometimes characterized by peaks in certain areas of intellect, artistic, or numerical ability, which occur in the context of an impoverished ability to manage and organize the tasks necessary for daily life. In general, the impact of executive dysfunction on an individual with autism varies according to the individuals' intellectual ability, capacity for independent functioning, and provision of social, emotional, financial, and later, occupational support. It has been suggested that individuals with associated intellectual disability and epilepsy are at greater risk for deterioration during early adulthood, while there may be some improvement in functioning in normally intelligent young adults with ASDs.

Frontal lobe syndrome or executive dysfunction is commonly linked to the repetitive, stereotyped behavioral patterns which are core diagnostic features of autism (Turner 1999). The repetitive behavioral patterns may be due to a difficulty inhibiting previously relevant response patterns, or may be due to a problem with generating new ideas and responses (Turner 1999). Common repetitive, restricted, and stereotyped behavioral patterns include: lining up toys or objects, being preoccupied with special objects such as stones, repeating play sequences, obsessions with train timetables or dinosaurs. Individuals with autism may have a number of rituals

associated with daily life, such as a fixed order for bathing and dressing, or an insistence on wearing the same clothes or taking the same route to a familiar place. These rituals go beyond what is normally seen in typically developing children. There are usually some motor mannerisms, such as hand flapping, or tiptoe walking and gait abnormality.

The symptoms of frontal lobe syndrome in autism cannot be neatly separated out from the broader network of behavior-brain disruptions which characterize autism. For example, children with autism may study the detail in a picture book or closely observe spinning wheels, or a ceiling fan; this may be due to problems with disengaging from interests (executive dysfunction), or it might be due to an overly developed visual-perceptual system which enhances the experience of looking at small objects (Plaisted et al. 1999). Similarly, a child with autism may have difficulty interacting with the peer group, not primarily because of social impairments related to "theory of mind" deficits, but perhaps because of an inability to shift attentional set from his or her own topics of interest. Therefore, a child with autism may engage in a monologue of speech about his favorite interests rather than a reciprocal dialogue with his peers either due to executive-based inflexibility, or due to a poor understanding that "turn taking" is required in productive social conversations (theory of mind deficit).

The clinical manifestation of frontal lobe syndrome may differ in girls with autism in a way which is consistent with gender-related differences in the typically developing population of male and female children. For example, while boys may have an intense preoccupation with vehicles, such as trains and cars, girls may develop their special interests in areas such as teddy-bear or doll collections, and spend unusual amounts of time on craft and art to the exclusion of other types of play. Gender-neutral activities, such as "drawing," may form the "special interest" for either males or females with autism. It has been suggested that females tend to have fewer special interests than males with autism (Gillberg and Coleman 2000), although this may relate to male interests being more circumscribed

(e.g., trains, cars) than female interests (e.g., craft, doll play), and thus more clinically salient.

Pathophysiology

Development of the frontal lobes is guided by regulatory genes which lay down and prune brain pathways (referred to as apoptosis), and set the timing of how the brain will be “wired” (referred to as synaptic connectivity). There is a disturbance in these regulatory genes in autism which results in atypically developing frontal regions. The current literature points to the developmental time course of brain development being the salient disturbance, rather than the “final product” of brain development in autism (Amaral et al. 2008, p. 137). The unfolding neurobiological disruptions which characterize autism may contribute to the changes in core symptoms of autism we see over time, such as stagnation and regression in social-communicative symptoms, and changes in the focus of obsessions and nature of repetitive behavioral patterns.

Bradshaw’s (2001) frontostriatal theory provides the most comprehensive review of the pathophysiology of “frontal lobe” syndrome in the context of neurodevelopmental disorders. According to this theory, the frontostriatal system involved in neurodevelopmental disorders comprises the dorsolateral prefrontal cortex, the lateral orbitofrontal cortex, the anterior cingulate, the supplementary motor area, and the basal ganglia. These areas are involved in a number of functions, such as executive functions (e.g., functions such as self-monitoring, planning, organization, flexibility of thinking, and inhibition), motivation, control of complex behaviors, and sequencing movements. A number of neurotransmitters are implicated in the frontostriatal system, including dopamine, nor-adrenaline, acetylcholine, GABA (inhibitory), glutamate (excitatory), and serotonin.

Evaluation and Differential Diagnosis

Frontal lobe syndrome (FLS) resulting from acquired brain injury involves impairment in

cognitive and/or mood domains that are presumed to be largely governed by neural circuitry involving the frontal lobe. This may include difficulties with planning, organization, daily living skills, attention, and social cognition. Individuals with FLS may be disinhibited and impulsive, and this can include aggression or inappropriate sexual, financial, or other behaviors. Depression, anxiety, and apathy are often also present. FLS in the purest sense is thought to arise from a lesion, be it from disease or trauma. This lesion can occur anywhere within fronto-striatal-thalamic circuitry, and the nature and degree of impairment is related to the site of injury. As noted above, FLS can also relate to neurodevelopmental, e.g., ASD and neurodegenerative disorders, e.g., Parkinson’s disease.

In addition to deficits in executive function, FLS syndrome can also involve impaired social functioning, including poor emotion recognition and theory of mind, and perseverative and repetitive behaviors. Individuals with FLS can also be quite rigid and concrete in their thinking. For these reasons, ASD is often referred to under the FLS umbrella. In addition, there is much evidence for executive deficits among individuals diagnosed with an ASD, and this can include problems with planning, time estimation, attentional set-shifting, and response inhibition.

Obtaining a thorough and careful developmental history is critical for differential diagnosis. Symptoms of FLS related to lesions typically have a relatively rapid onset, and are recognized because they are uncharacteristic of the individual. ASD, on the other hand, generally must first present within certain time periods, and there is emerging evidence to suggest that some symptoms are present in infancy. When assessing individuals later in life (e.g., adolescence onward), it is crucial to involve family members in the diagnostic process, and to conduct a structural magnetic resonance imaging (MRI) brain scan.

Assessment for autism spectrum disorder (ASD) should include neuropsychological testing, which at a minimum would involve an age-appropriate, standardized cognitive assessment, but perhaps also tests of executive function. This might include inhibitory controls (e.g., word-color Stroop test), attentional set-shifting

(e.g., Wisconsin Card Sorting Test), and planning/organization (e.g., Tower of Hanoi, Trail making test). Verbal fluency assessment may also be used (e.g., FAS). This will characterize an individual's strengths and weaknesses, and allow clinicians to devise an appropriate treatment plan that meets the individual's needs. For very young children, or those for whom standardized assessment is not possible, parent and teacher report can provide insights into relative strengths and weaknesses, including problematic behaviors.

Treatment

The best outcomes for managing clinical symptoms associated with executive impairment in autism are produced by a combination of psychological, educational, and medical approaches if indicated. Treatment should be designed to target the specific needs of an individual child and also to meet the needs of parents and schools (Tonge and Rinehart 2006).

Psychosocial

Training in problem solving and organizational skills can be useful for targeting difficulties with generating new or novel behaviors and moving the individual away from rigid thinking styles. Interventions which capitalize on a child's special interests, for example, technology, may improve compliance. Reminders, schedules, visual prompting (e.g., when I finish playing trains, I can choose from a list of these activities to do), and executive-function "scaffolding" by care-givers, (e.g., breaking down tasks into smaller components, helping individuals to structure daily events to prevent becoming submerged in one activity during the day, assisting with school-based tasks) are often helpful.

Pharmacological

Drugs might be prescribed where psychological and behavioral interventions have not been

successful in the management of disturbed emotions and behaviors, in particular, repetitive self-injurious behaviors which place children at greater psychological and physical risk. There is some evidence that neuroleptic medication (e.g., haloperidol, risperidone) reduces repetitive and stereotyped behaviors; however, it may produce side effects including sedation, dystonic reactions, and increased weight gain. Unlike the original neuroleptic medications, new atypical drugs are not associated with the risk of irreversible tardive dyskinesia. Tricyclic antidepressants (e.g., imipramine, clomipramine) are effective anxiolytics, and may also reduce repetitive behaviors, but may have potential cardiotoxic effects (Tonge and Rinehart 2006). Parents may be stressed by the uncertainty of potential long-term effects of placing their child on medication. Currently there is a lack of good long-term evidence for the effectiveness of stimulant medication on learning but they may decrease the risk of later substance abuse (Tonge and Rinehart 2006).

Functional Analysis Screening Tool

Robert H. LaRue

Douglass Developmental Disabilities Center,
Rutgers, The State University of New Jersey,
New Brunswick, NJ, USA

Synonyms

FAST (Functional Assessment Screening Tool)

Description

The FAST is a type of indirect functional assessment method. It is comprised of a self-report checklist designed to identify whether maladaptive behavior is maintained via attention and tangibles, escape, sensory stimulation, or pain attenuation.

Prior to the rating scale section of the instrument, the FAST has two information sections: Informant-Client Relationship and Problem Behavior Information. The Information-Client Relationship section contains four questions regarding the informant-client relationship (e.g., relationship to the client, how often and in what situations they interact). The Problem Behavior Information section contains eight questions regarding the topography, frequency, and severity of the target behavior.

The checklist section contains 16 items. Each question is marked as either “yes,” “no,” or “not applicable.” Items endorsed with a “yes” are then categorized into one of the four possible sources of reinforcers for problem behavior: attention/preferred items (social positive reinforcement), escape (social negative reinforcement), sensory stimulation (automatic positive

reinforcement), and pain attenuation (automatic negative reinforcement). Behavioral function is inferred by calculating a summary score for the four possible maintaining variables. The FAST interview process is 10–15 min in length.

Historical Background

The FAST was originally developed in 1995, as an adjunct to functional analysis procedures. The scale underwent several revisions before the most recent version, which was released in 2005. The initial scale included 34 items. After field-testing the FAST with over 300 individuals, the item pool was reduced to the present 16 items.

Psychometric Data

Psychometric data for the FAST are generally sparse. Zaja et al. (2010) evaluated and compared the psychometric properties of the Questions About Behavioral Function (QABF) scale (Matson and Vollmer 1995), the Functional Assessment for Multiple Causality (FACT) scale (Matson et al. 2003), and the FAST for the indirect assessment of self-injurious, stereotypic, and aggressive/destructive behavior. The FAST subscales generally showed the lowest inter-rater agreement with correlations ranging from poor to good relative to the QABF and FACT. Zaja et al. also found that the FAST had unacceptably low internal consistency especially for the social attention and social escape subscales. The authors indicated that the weaker psychometrics properties (reliability and validity) for the FAST were likely related to its length, limited response format (“Yes”/“No”/“NA”), and restricted range of subscales (4 instead of 5).

Iwata et al. (2013) evaluated the reliability and validity of the FAST. In the first study, the authors assessed the interrater reliability of the FAST with 196 problem behaviors through independent administration of the assessment to pairs of raters. The average item-by-item agreement between pairs of raters was 71.5%, with a range of 53.3–84.5%. In the second part of the

investigation, the authors compared the results of the FAST to the results of 69 functional analyses. The authors found that the FAST predicted the primary function of challenging behavior 63.8% of the time. The authors note that, while the results are comparable to other indirect assessment tools, they are not an adequate substitute for functional analysis procedures.

Clinical Uses

The FAST is an indirect functional assessment procedure. The purpose of the instrument is to provide preliminary information regarding the cause (of function) of maladaptive behavior. The information gathered from the FAST can be incorporated into direct assessment methods. Given the questionable reliability of most indirect assessment measures (such as interviews and rating scales), it is often recommended that these methods be employed in conjunction with direct observation and/or functional analysis procedures and not as the sole means to determining behavioral function (Zarcone et al. 1991).

Functional Analysis: Assessment Procedures for Complex Challenging Behavior

Mark Palmieri¹ and Kimberly Marshall²

¹Feeding Clinic, Center for Children with Special Needs Glastonbury, CT, USA

²Center for Children with Special Needs, Glastonbury, CT, USA

Definition

Assessing behavior through data-based collection procedures is a necessary component of applied behavior analysis (Cooper et al. 2007). The primary goal is to establish a reliable relationship between the treatment and behavior change. This concept forms the basis for the assessment of challenging behavior in applied behavior analysis. Functional analysis is the procedure by which environmental conditions are manipulated to reliably evoke a target behavior (Carr and Durand 1985; Cooper and Harding 1993; Iwata et al. 1982/1994a, 1990; O'Reilloy et al. 2009; Roscoe et al. 2010). Based upon the results of these assessments, maladaptive behavior is conceptualized as being motivated by a particular function, thus allowing appropriate interventions to be developed. An important component of functional analytic methodology is that behavior must be understood by its consequences within the environment and not solely by its topography or form (Cooper and Harding 1993). The majority of functional analysis procedures currently used are based upon the seminal work of Iwata et al. (1982/1994a).

Functional analysis methodology has been applied to a variety of treatment settings. The original research on these procedures was conducted in highly controlled treatment settings (Carr and Durand 1985; Cooper and Harding 1993; Iwata et al. 1982/1994a, 1990). In these environments, experimenters have exposed participants to repeated treatment conditions in order to establish a reliable relationship between environmental contingencies and the occurrence of a target behavior (Carr and Durand 1985; Iwata et al. 1982/1994a, 1990). Research attention has expanded toward evaluating the use of functional analytic procedures in outpatient and community-based settings with less precise and sustained control (Cooper and Harding 1993). Further, functional analytic models have evolved to include a variety of brief methodologies which have gained substantial evidence-based support (e.g., LaRue et al. 2010; Thomason-Sassi et al. 2011). The ongoing research on functional analysis continues to provide a great deal of support for its methods to represent the best practice means of assessing challenging behavior (e.g., Cooper et al. 1992; Derby et al. 1992, 1994; Ruiz and Kubina 2017).

Historical Background

Carr (1977) established the conceptual foundation for functional analysis. The model for clinical practice is associated with the work of Iwata et al. (1982/1994a) and Carr and Durand (1985). The methodology developed in these studies has since been widely examined and used in the applied behavior analysis literature (Hanley et al. 2003). The initial study by Iwata et al. (1982/1994a) utilized four assessment conditions to evaluate self-injurious behavior in nine individuals diagnosed with developmental disability, ranging in age from 19 months to 17 years and 2 months. The conditions included in the functional analysis were social disapproval, academic demand, unstructured play, and alone. During the assessments, conditions lasted for 15 min and were randomly ordered for each participant. The functional analysis continued until stable levels of responding were observed in each condition, or until 12 days of assessment were completed.

The social disapproval condition was designed to replicate contingencies for positive reinforcement in the form of attention for engaging in self-injury. The participant was instructed to play with toys while the experimenter worked. If the participant engaged in self-injury, the experimenter provided physical and vocal attention. The academic demand condition tested for the presence of negative reinforcement contingencies in the form of escape from work for engaging in self-injury. The experimenter ran academic programs appropriate to each participant's ability level. Social praise was delivered after each response whether or not the response was correct. If the participant engaged in self-injurious behavior, the experimenter turned away and terminated the learning trial. The alone condition was designed to assess for self-injurious behavior maintained by automatic reinforcement. The participant was left alone without access to attention or tangible items. The experimenter did not provide a consequence for an occurrence of self-injury. Finally, the unstructured play condition served as a control condition for the functional analysis. In this condition, the experimenter provided noncontingent attention and access to toys and gave no demands. Again, no consequence was provided contingent upon an occurrence of self-injury.

Operational definitions were created for each participants' topography of self-injury to address individual differences. Interobserver agreement was calculated to ensure that all observers were able to reliably identify all the topographies of challenging behavior. The results of the Iwata et al. (1982/1994a) study demonstrated that similar topographies of behavior can serve different functions. In their study, the level of responding varied from individual to individual across the assessment conditions. As a result of these data, Iwata et al. (1982/1994a) supported functional analysis as a means of systematically evaluating the stimuli maintaining behavior and subsequently the use of individualized assessment and intervention procedures for self-injurious behavior.

Carr and Durand (1985) echoed the Iwata et al. (1982/1994a) results, showing that similar forms of challenging behavior can be maintained by

different contingencies in each individual. The study evaluated a number of topographies of challenging behavior experienced by four participants, ages 7–14 years, with either developmental disabilities or brain damage. The functional analysis conditions were designed to assess escape and attention motivations for each target behavior. The "easy 100" condition served as the control condition for the analysis. In this condition, the experimenter provided easy demands and attention during 100% of the condition's intervals. In the "easy 33" condition, the experimenter again utilized easy demands but only provided attention during 33% of the intervals. This condition was used to assess for an attention motivation for each target behavior. During the "difficult 100" condition, the participants were given challenging demands and attention during 100% of the condition's intervals. It was expected that this condition would assess for an escape function maintaining any target behavior.

Consequences were provided for all topographies of behavior in the same manner during each condition. All behavior except darting and responses that risked physical injury were placed on extinction (Carr and Durand 1985). If the participant darted from work and did not return in 10 s, she or he was physically guided back to the table. In cases where physical risk was a concern, the participant's hands were restrained for 5–10 s while the experimenter followed through with the work demands. The results of the functional analyses suggested that the various forms of challenging behavior of the participants were maintained by different environmental contingencies. The data from the Carr and Durand study supported those obtained by Iwata et al. (1982/1994a). That is, functional analysis was endorsed as a means for evaluating challenging behavior.

Carr and Durand (1985) further supported functional analysis as a means of assessing and treating challenging behavior by implementing functional communication training for each of the participants. The target of the training was requests for attention and help as a replacement for challenging behavior reinforced by attention and escape, respectively. By providing consistent reinforcement for appropriate requests for

attention and help, all participants' challenging behavior decreased. Functionally equivalent interventions were thereby supported as the optimal treatment for challenging behavior.

Contemporary Considerations

A great deal of research has been conducted on functional analysis methodology since the seminal studies by Carr and Durand (1985) and Iwata et al. (1982/1994a). Systematic reviews of the literature on functional analysis have consistently supported the procedure's efficacy in both identifying the function of challenging behavior and determining effective replacement skills (e.g., Hanley et al. 2003, 2014; Iwata et al. 1994b; LaRue et al. 2010; O'Reilloy et al. 2009; Thomason-Sassi et al. 2011). Hanley et al. (2014) reviewed 575 functional analysis studies, 96% of which rendered usable outcomes. While the functional analysis procedures utilized in typical studies are rarely identical, the basic premise of controlled antecedents and consequences as defined by environmental manipulations has aided in the development of functionally equivalent interventions that have shown a decrease in problem behavior and an increase in targeted replacement skills (Hanley et al. 2014; Iwata et al. 1994b).

Hanley et al. (2003) reviewed the literature to identify trends for best practices in functional analysis methodology. Their review supported the use of functional analysis to study many topographies of challenging behavior in individuals with disabilities of varying severities. While a substantial portion of the literature has focused on learners with developmental disabilities or intellectual disability, it is important to note that a variety of other mental disorders and mild behavior problems have been included in analyses (e.g., Cooper et al. 1990; Doggett et al. 2001).

The experimental conditions most prevalent in the literature for analogue functional analyses are developed based upon those used by Iwata et al. (1982/1994a). These conditions, social positive reinforcement (attention), social negative reinforcement (escape), automatic reinforcement

(alone), and control, appear as they were described above. In addition, a tangible condition has been applied to in a number of studies (e.g., Fisher et al. 2000; Moore et al. 2002a; Mueller et al. 2001; Shirley et al. 1999). In this condition, the individual is given access to a highly preferred item for 1 min at which point the experimenter removes the item and places it out of reach (Mueller et al. 2001). The participant is told that the target item is unavailable and directed toward other low-preference items. Upon the occurrence of the target behavior, the experimenter grants access to the high-preference item. These variables have continued to be incorporated into the conditions of subsequent functional analysis models (e.g., trial-based or response latency; LaRue et al. 2010).

Several concerns are common in developing the conditions for a functional analysis. These concerns often focus on the presence of confounds in the assessment conditions (Hanley et al. 2003; Moore et al. 2002a; Shirley et al. 1999) as well as the challenges of repeatedly evoking challenging behavior (e.g., Thomason-Sassi et al. 2011). Hanley et al. (2003) noted that while there are not universal firm rules for functional analysis, certain components have been identified that can be considered among best practices. Included here are factors such as limiting assessment to a manageable number of responses, considering the influence of establishing operations on the contingencies active in each condition, relatively short sessions, brief designs that can be expanded on an individual basis, and programming for consequences (Hanley et al. 2003).

Concerns regarding session confounds are common. For example, such challenges were illustrated by Moore et al. (2002a) regarding the influence that attention can play during a tangible condition. A functional analysis was conducted on a child's self-injurious behavior (SIB). The results of the analysis suggested that SIB was a multi-operant behavior maintained by positive reinforcement in the form of attention and access to preferred items (Moore et al. 2002a). In a follow-up analysis, the level of attention provided during the tangible condition was evaluated. By reducing the amount of attention paired with the

presentation of the tangible, the rate of SIB was decreased. Moore et al. (2002a) suggested that the attention inadvertently delivered during the tangible condition was acting as a confound and evoking SIB. Weakening the contingency between the target behavior and access to attention (e.g., delivering attention noncontingently) may serve to control for the influence of confounds (Moore et al. 2002a). If the contingent presentation of attention does confound the tangible condition, it stands to reason that all independent variables should be carefully controlled during the development of functional analysis sessions.

Another similar methodological concern was identified by Shirley et al. (1999) in a study on incidental maintenance in the tangible condition. A functional analysis conducted on an individual's hand mouthing suggested that the behavior was maintained by automatic reinforcement and access to tangible items. Observations of the behavior indicated that the preferred items used in the assessment were almost never provided as a natural consequence. Therefore, the functional analysis may have identified a tangible function that was not actually maintaining challenging behavior but rather could have maintained behavior if it were presented contingently (Shirley et al. 1999). Shirley et al. suggested caution when using the results of a preference assessment without collecting some form of data on the natural environment.

Application across diverse settings and brief session durations have gained increased attention in recent years as pressing topics requiring investigation in the area of functional analysis methodology. There is now a growing literature base demonstrating the use of functional analysis in less controlled settings such as schools and outpatient clinics (e.g., Cooper et al. 1992; Cooper and Harding 1993; Iwata et al. 2000; LaRue et al. 2010; Moore et al. 2002b; Ruiz and Kubina 2017; Thomason-Sassi et al. 2011; Umbreit 1995). To be useful within a diverse array of settings, considerations related to the efficient application of functional analysis procedures must be addressed.

A study by Wallace and Iwata (1999) considered the influence of session duration on determining function. Forty-six individuals

participated in functional analyses based on the model described by Iwata et al. (1982/1994a). Tangible conditions were also run for those individuals whose indirect assessment suggested that access to tangible items might evoke the target behavior. The sessions were videotaped, and three sets of data were prepared for each participant, by using the first 5, 10, and 15 min of the sessions. Trained independent raters evaluated data from each video. The results rendered strong agreement between the 15- and 10-min sessions and only three disagreements between 15- and 5-min sessions. As a result, shorter session duration was supported as a means for increasing the practical application of functional analysis methodology (Wallace and Iwata 1999). Similarly, LaRue et al. (2010) and Thomason-Sassi et al. (2011) both identified efficiencies in models applying limited session durations while maintain a high degree of correspondence with traditional analogue findings.

Another concern regarding functional analysis conducted in controlled clinical settings where naturally occurring environmental events are much less likely to influence assessment conditions is that the functional analysis may suggest a relationship that does not exist in the natural environment (Hanley et al. 2003). This phenomenon may compromise the ecological validity of the findings. In addition, a long-standing factor in treatment is that most individuals referred for treatment are not admitted directly to inpatient facilities. Typically intervention attempts on an outpatient basis constitute the first stage of treatment (Cooper et al. 1990). By developing a model compatible with an outpatient treatment facility and using parents during a functional analysis, Cooper et al. (1990) were able to identify the functions maintaining different topographies of challenging behavior and develop successful treatment interventions. This research has continued extensively, and a growing body of research has demonstrated the use of functional analysis procedures in a variety of treatment settings such as outpatient clinics, schools, and homes (e.g., Cooper and Harding 1993; Cooper et al. 1990; Doggett et al. 2001; LaRue et al. 2010; Thomason-Sassi et al. 2011; Umbreit 1995).

Doggett et al. (2001) and Umbreit (1995) tested the application of functional analysis methodology in classroom environments. Their studies focused on developing a process in which the conceptual foundations of applied behavior analysis were incorporated with an efficient use of classroom resources. Similar to Cooper et al. (1992) and Cooper and Harding (1993), Doggett et al. and Umbreit suggested the use of indirect data collection procedures, as well as descriptive analyses and observations, to aid in the interpretation of functional analysis data; however, the use of such data has not been consistently shown to have high agreement with objective functional analysis outcomes (e.g., Paclawskyj et al. 2008; Zarccone et al. 1991). While correspondence between indirect methods and functional analysis conditions may be low, it has been suggested that such procedures may increase the ecological validity of the analysis (e.g., Fisher et al. 2016).

Another pressing issue in the development of functional analysis methods has been the ability to engage multiple participants in the implementation of conditions. This is particularly relevant for those analyses conducted outside of highly controlled clinical settings. In the Doggett et al. (2001) study, behavioral consultants assisted general education classroom teachers in conducting an entire functional assessment. The functional analysis component of the assessment was implemented during periods of general classroom instruction. Behavioral consultants trained and supervised the entire assessment procedure, ensuring that the teachers played a primary role in hypothesis development and data analysis. Similarly, in Umbreit (1995), a teacher was supported in the implementation of a functional analysis that proved successful in identifying a function of the student's challenging classroom behavior. In a review of trial-based functional analysis models, Ruiz and Kubina (2017) found that teachers and paraprofessionals were able to implement conditions and that the training for this could occur in short intervals. The successful implementation of functional analysis in a variety of settings and with individuals who only require brief training to implement conditions further demonstrates the technology's use outside of

controlled inpatient clinics (Cooper and Harding 1993; Doggett et al. 2001; Umbreit 1995; Ruiz and Kubina 2017).

Future Directions

In addition to modifications to session duration and implementor, changes to session structure have been introduced and are increasingly common (e.g., Bloom et al. 2011; Hanley et al. 2014; LaRue et al. 2010; Thomason-Sassi et al. 2011). Thomason-Sassi et al. found that in latency functional analyses where 5-min sessions were used and where the conditions were terminated immediately following implementation of a consequence, that nine of ten cases showed correspondence between this brief format and standard analyses. Similarly, multiple investigations of trial-based functional analysis models have found strong correspondence with transitional formats. Such models tend to deploy brief conditions that terminate after the first occurrence of a challenging behavior and are either preceded or followed by a condition-specific control phase (or motivating operation absent phase). LaRue et al. compared standard analyses with trial-based methods which implemented conditions of 1–2 min in length and found exact correspondence in four of five participants, with partial correspondence found in the fifth case. Similarly, Bloom et al. (2011) determined trial-based functional analysis to be a viable method, particularly for assessments conducted within natural routines and when more standard analysis would not be feasible. As trial-based methods have gained increasing attention in the literature, Ruiz and Kubina (2017), in an analysis of 17 trial-based studies, found a number of benefits to these models such as implementation within the typical day, few repetitions of severe behavior, shorter session durations, and ease of training implementors.

Ongoing efforts to further improve the efficiency and social validity of functional analyses also include investigations to incorporate functional assessment interviews and observations to directly inform the development of the functional analysis (Hanley et al. 2014). This suggests that

synthesizing multiple assessment and treatment elements within conditions can improve outcomes and the social validity of the analyses. However, Fisher et al. (2016) questioned the benefits of synthesized conditions, including any improvements achieved through use of open-ended interviews. Though they did note the potential for improved ecological validity from such efforts. This area of development in functional analysis remains actively debated and subject to ongoing research investigations.

Functional analysis is considered among the most efficient assessment technologies as it provides data on demonstrated relationships between environmental events and target behavior. This allows for the development of behavior intervention and teaching plans that are precisely crafted to the needs of the individual. Functional analytic methods enable investigators to control confounding environmental variables that make direct observation-based assessments often very difficult. For example, difficulties discriminating whether escaping a difficult demand or gaining access to direct teacher attention is the most relevant feature of a student's noncompliant behavior. Using functional analysis, these variables are precisely controlled. The demonstrated relationship between environmental triggers and behavior leads to therapeutic interventions that are functionally driven and evaluable. As methods have expanded to include brief and naturally embedded methods, the impact of functional analysis across both research and practice communities has grown substantially.

Functional Assessment and Curriculum for Teaching Everyday Routines

John Molteni
Institute for Autism and Behavioral Studies,
University of Saint Joseph, West Hartford,
CT, USA

Definition

The Functional Assessment and Curriculum for Teaching Everyday Routines (FACTER) is a criterion-referenced assessment and curriculum for teaching daily routines and activities of daily living. It is designed to address the needs of individuals with developmental disabilities. FACTER provides task-analyzed skills that cover a variety of skills needed to navigate an individual's daily environment. There are two versions of FACTER, an elementary level and secondary level. Both consist of formative and summative assessments

of student learning and provide a framework for developing and tracking instruction across routines.

Historical Background

The history of FACTER is outlined in the Program Manual (Arick et al. 2000). FACTER was developed to meet the requirements of the Individuals with Disabilities Education Act Amendments of 1997. The first iteration, named the Extended Career and Life Role Assessment System (Arick et al. 2000), was designed to assess individuals who were not participating in statewide or district assessments and meet the state standards for career-related learning. There were several features of the Extended CLRAS that allowed the state of Oregon to meet IDEA mandates for reporting assessment results.

The first version of FACTER was an extension of the Extended CLRAS that added the instructional component. Individualized lesson plans were added to assist educators in developing instructional programs that complemented the assessments conducted for program planning and assessing progress on intervention goals and objectives. Progress monitoring was added to support ongoing instructional development and modification and track the effectiveness of interventions. Skills targeted for assessment and instruction were derived from special education standards and areas of functioning referenced in the literature and clinical practices as important for independent living.

Rationale or Underlying Theory

The primary rationale for FACTER is the development of skills that will maximize independent skill development, a primary goal of special education. Assessment of skills and instructional practices are developed to maximize student independence and allow for a complete assessment to goal development and instructional planning to implementation of instruction. The underlying

instructional theory is that of direct instruction utilizing task analytic approaches to instruction. Additional strategies utilized during instruction include visual supports, tactile systems, and social stories. Preteaching of routines and instruction during the routine are implemented during instruction. Criterion-referenced assessment is a critical feature of this program with skills that are broken down into smaller component skills that allow for analysis and progression through the sequence of behaviors necessary to independently perform the skill.

Goals and Objectives

The goals and objectives of FACTER are related to the instruction of routines and underlying skills related to those routines to enhance a student's independent living skills. Individualized goals and objectives are developed based on results obtained in the FACTER assessment phase. Subsequently, lesson plans based on these objectives are developed and implemented utilizing direct instructional approaches. Ongoing data collection is utilized to track individual's progress as well as report the results of larger groups of students. Individual student tracking allows for adjustment of instructional programming in response to student performance. Summative assessment utilizing criterion-referenced assessment allows for reporting on Individualized Educational Plans and for statewide and district-wide assessments.

Treatment Participants

FACTER is designed for individuals who require special education services with a particular focus on individuals in need of life skills training and those that are not participating in statewide or district-wide assessments. A particular focus is on developing skills that maximize student independence and align with state educational standards for post-secondary skills that support career, independent living, and involvement within society as a responsible citizen.

Treatment Procedures

There are three components outlined in the FACTER manual related to treatment procedures. These are:

Assessment Phase

This phase consists of utilizing the Program Manual of FACTER to assess the individual's ability across a variety of domains. These include Living Skills, Transition, Academic, Leisure, and Community at the elementary level with the addition of Career as a domain in the secondary level. During the assessment phase, the educator obtains baseline ratings of routines on a 5-point scale from 0 (does not complete with physical assistance) to 4 (completes independently). An N can be used to indicate Not Applicable which may be due to physical or medical limitations that prevent the student from engaging in the routine or indicates that the routine is deemed inappropriate by the educational team or is not supported by the school environment. Baseline ratings are completed by individuals who are familiar with the student being assessed.

Following the baseline ratings, routines are selected for performance assessment. Corresponding skills related to completion of the routine are also selected. Skill areas include expressive communication, receptive communication, problem solving, teamwork/social skills, motor skills, and functional academics. These are subsequently broken down from basic to complex. All selections in this step are made on the basis of IEP goals and objectives developed by the educational team. The criterion for selection is that if completed, these skills will lead to increased independence by the student. Data are collected via direct observation on these routines and skills and are charted in the student booklets included with the Program Manual.

Instruction Phase

This phase includes a variety of instructional strategies that can be utilized by educators to instruct students on independence of routines

selected in the assessment phase. Routines are typically taught in inclusive settings, with transition routines integrated between routines from other domains. That is, when a routine in the classroom involves an academic task, then a transition to group instruction, the educator strings these three routines (academic, transition, social) together. Taken as a whole, increasing independence on these routines allows the student to be better able to navigate a typical environment with as little assistance as possible. This includes strategies of prompting and prompt fading to increase independent functioning. Instruction before the routine is executed (pre-routine instruction) and instruction within the routine follows. Location of this instruction is relevant to the individual's ability to execute the skills in the natural environment.

Steps described by the authors include prioritizing instructional objectives, providing instruction and assessing progress, and conducting performance assessment of routines following instruction. During the first step, educators choose teaching strategies to utilize with the student with specific setup, and teaching suggestions are outlined in the Program Manual. Instructional strategies are grouped into categories such as creating cues, creating pictures, fine and gross motor skills practice, modeling, picture storybook, role playing, social stories, tactile systems, and visual systems. Ongoing assessment occurs with direct observation data collection which indicates what strategies were used and what outcomes were achieved by the student. Assessments are conducted after several teaching sessions in a probe format. The final step involves a performance assessment of the student's performance on the routine. This is the fourth assessment of the routines following instruction and ongoing performance assessment.

Evaluation Phase

This phase involves determining whether to continue instruction or return to the assessment phase. The Program Manual provides guidelines for determining which decision to make. Continuing

with the instruction phase is warranted if the student has not met the criteria of mastery in the instructional phase. There are several conditions that can be used to terminate current instruction. These involve mastery of the routines and meeting the instructional goals of the student's individualized education plan that may not be at the level of independent functioning. That is, if a student has progressed by way of decreased dependence on teacher support, this may meet the goals set forth by the educational team. Finally, instruction may be discontinued in several instances, including student's lack of progress and environmental limitations that do not support ongoing instruction.

Efficacy Information

There are no empirical studies to date that outline the efficacy of FACTER in educational settings, although the Program Manual references some unpublished research. The Program Manual does provide data that was collected during field testing of FACTER in the state of Oregon through the Department of Education. Interrater reliability and test-retest reliability were reported with high correlation coefficients reported for elementary and secondary levels. These were somewhat lower for secondary scores and ratings between teachers and assessment team raters.

Concurrent validity was assessed with the Vineland Adaptive Behavior Scales – Interview Edition and correlations between teacher ratings on FACTER and actual student performance. Correlation coefficients in both cases were adequate.

Outcome Measurement

Outcomes on FACTER are assessed for each individual on the routines that are the target of instruction. Assessments indicate level of independent performance. Please see the "Treatment Procedures" section for additional information on the assessment and evaluation procedures of FACTER.

Qualifications of Treatment Providers

FACTER is intended for use by special educators in a school setting, although no specific recommendations are made for individuals who may administer the FACTER or implement the teaching procedures. While the authors provide the necessary tools to utilize the curriculum, they do offer training and technical assistance to users.

Functional Assessment Screening Tool (FAST)

Robert H. LaRue
Douglass Developmental Disabilities Center,
Rutgers, The State University of New Jersey,
New Brunswick, NJ, USA

Synonyms

FAST (functional assessment screening tool)

Description

The FAST is a type of indirect functional assessment method. It is comprised of a self-report checklist designed to identify whether maladaptive behavior is maintained via attention and tangibles, escape, sensory stimulation, or pain attenuation.

In addition to the checklist, the FAST is comprised of two information sections: informant-client relationship and problem behavior information. The informant-client relationship section contains four questions regarding the informant-client relationship (e.g., relationship to the client, how often and in what situations they interact). The problem behavior information section contains eight questions regarding the topography, frequency, and severity of the target behavior.

The checklist section contains 16 items. Each question is marked as either “yes,” “no,” or “not applicable.” Items endorsed with a “yes” are then categorized into one of four possible sources of reinforcers for problem behavior: attention/preferred items (social positive reinforcement), escape (social negative reinforcement), sensory stimulation (automatic positive reinforcement), and pain attenuation (automatic negative reinforcement). Behavioral function is inferred by calculating a summary score for the four possible maintaining variables. The FAST interview process is 10–15 min in length.

Historical Background

The FAST was originally developed in 1995, as an adjunct to functional analysis procedures. The scale underwent several revisions before the most recent version, which was released in 2005. The initial scale included 34 items. After field-testing the FAST with over 300 individuals, the item pool was reduced to the present 16 items.

Psychometric Data

Psychometric data for the FAST are generally sparse. Zaja et al. (2010) evaluated and compared the psychometric properties of the Questions About Behavioral Function (QABF) scale (Matson and Vollmer 1995), the Functional Assessment for Multiple Causality (FACT) scale (Matson et al. 2003), and the FAST for the indirect assessment of self-injurious, stereotypic, and aggressive/destructive behavior. The FAST subscales generally showed the lowest inter-rater agreement with correlations ranging from poor to good relative to the QABF and FACT. Zaja et al. also found that the FAST had unacceptably low internal consistency especially for the social attention and social escape subscales. The authors indicated that the weaker psychometrics properties (reliability and validity) for the FAST were likely related to its length, limited response format (“yes”/“no”/“NA”), and restricted range of subscales (4 instead of 5).

The FAST was evaluated by Iwata et al. (2013) for reliability and validity. Interrater reliability was assessed for 196 problem behaviors through independent administration of the assessment to pairs of raters. The average item-by-item agreement between pairs of raters was 71.5%, with a range of 53.3% to 84.5%. The authors also compared the results of the FAST to the results of 69 functional analyses. They concluded that the FAST predicted the primary function of challenging behavior 63.8% of the time. The authors noted that, while the results are comparable to other indirect assessment tools, they are not an adequate substitute for functional analysis procedures.

Clinical Uses

The FAST is an indirect functional assessment procedure. The purpose of the instrument is to provide preliminary information regarding the cause (of function) of maladaptive behavior. The information gathered from the FAST can be incorporated into direct assessment methods. Given the questionable reliability of most indirect assessment measures (such as interviews and rating scales), it is often recommended that these methods be employed in conjunction with direct observation and/or functional analysis procedures and not as the sole means to determine behavioral function (Zarcone et al. 1991).

Definition

Functional behavior assessment (FBA) procedures are used to investigate the maintaining variables associated with a target response and identify adaptive responses to be taught in order to allow the individual to better meet his or her needs. There are a variety of assessment procedures associated with the completion of a comprehensive FBA. These may be categorized into indirect and direct measures. Indirect procedures will capture archival information about the patient and allow those who are familiar with the individual and the target response to offer reports. Completion of indirect interviews and questionnaires allows investigators to capture information from many sources in a generally time-efficient fashion. The information gathered through indirect methods enables investigators to develop a comprehensive conceptualization of the target behavior for the assessment, as well as to capture information relevant to understanding the patient's needs, life context, learning history, motivators, and interpersonal support system. This information allows investigators to gain insight into common environmental variables associated with the target behavior, specifically including both high- and low-probability contexts. Indirect data collection tools will address environmental variables such as locations, times of day, individuals present, engagement, demand levels, access to preferred materials, and characteristics (e.g., sensory variables) of different

environments. Direct data collection is a required feature of any FBA. The observations must be guided by an operational definition of the target response for the assessment, and all observers must be trained to levels of acceptable reliability on the target. Direct data should be captured across multiple contexts in order to capture a sufficiently comprehensive data set for analysis. This typically includes observations across multiple days, times of day, and settings (e.g., high- and low-demand environments and high-, low-, and divided-attention environments). Antecedent behavior consequence (ABC) data are among the most commonly collected direct observation data when completing an FBA. These data require the observer to record information on the general environmental context and the exact changes that occurred immediately before and after the occurrence of the target response. The data are analyzed in order to determine common classifications of antecedent and consequence events associated with the target behavior. This information is then reviewed with all other sources of information collected during the assessment in order to develop a functional hypothesis of the maintaining variables for the challenging behavior and to map replacement skills to teach during intervention phases.

Definition

Functional behavior-based cognitive-behavioral therapy (CBT) for obsessive-compulsive behavior (OCB) in the pediatric population is a blending of two disciplines: (a) CBT with cognitive, social, and linguistic adaptations tailored to the specific needs of children and youth with autism spectrum disorder (ASD) and (b) functional behavior assessment and intervention derived from applied behavior analysis (ABA) to address perceived maintaining variables of target compulsions (e.g., positive social attention) that are beyond anxiety reduction. Working in combination, the two disciplines of CBT and ABA may allow for a more comprehensive treatment of overt and covert behaviors that comprise OCBs in children and youth with ASD.

Historical Background

In comparison to social-communicative challenges characteristic of ASD (DSM-5; American

Psychiatric Association 2013), research on restrictive and repetitive behaviors (RRBs) is limited. Factor analytic studies reveal two broad subtypes, including lower-order RRBs (e.g., self-injury, echolalia, motor stereotypy) and higher-order RRBs (e.g., washing rituals, rigid routines, arranging, and ordering). This limited research is troubling given that these behaviors may have negative effects on educational and social outcomes for individuals with ASD, are linked to increased parental stress, and often negatively impact family functioning (Boyd et al. 2012). Studies have used the Repetitive Behavior Scale-Revised (RBS-R; Bodfish et al. 1999) which is a 43-item parent report measure of RRB frequency and severity with good psychometric properties for individuals with ASD and related disabilities. Studies reveal preliminary support for higher-order RRBs (compulsive, ritualistic, and insistence on sameness behaviors) in ASD loading on the same factor (Mirenda et al. 2010), with many higher-order behaviors (e.g., arranging and ordering) showing topographic similarities to symptoms that are characteristic of obsessive-compulsive disorder (OCD, DSM-5; APA 2013). Studies acknowledge overlapping symptom presentation in individuals with ASD and OCD, with common phenotypic and genetic factors in these disorders (Stone and Chen 2016). OCD is defined by the presence of persistent thoughts, urges, or images that elicit anxiety and the overt display of repetitive behaviors or mental acts (compulsions) that an individual feels the need to perform to mitigate anxiety or in response to a rigid rule (APA 2013).

When conducting a diagnostic assessment of OCD in a child or youth with ASD, differentiating between higher-order repetitive behaviors related to ASD and symptoms that are characteristic of OCD can often be problematic. Given challenges in the ability to engage in expressive communication with others as well as limited self-reflection and introspection, it may be difficult for children and youth with ASD to identify and describe their obsessions and compulsions that is an integral part of standardized assessments such as the Child Yale-Brown Obsessive-Compulsive Scale (CY-BOCS; Goodman et al. 1986). The

CY-BOCS is a semi-structured interview comprised of 10 items and is used to rate symptom severity on a five-point ordinal scale. This measure has good psychometric properties for individuals who are 6–17 years old and otherwise typically developing. However, assessment tools such as the CY-BOCS (Goodman et al. 1986) are not specifically normed for children and youth with an ASD diagnosis. Also, different from OCD in typically developing individuals, research indicates that compulsive behaviors in ASD may or may not be strongly associated with obsessions, and strength of association may vary for any given compulsion (Ruzzano et al. 2015). Therefore, when customizing therapy to a given individual, it is of utmost importance that, in addition to diagnostic assessment tools, consideration be given to other assessment methods such as functional behavior assessment in order to identify motivating factors and maintaining variables beyond anxiety reduction such as positive sensory stimulation (automatic reinforcement) and social attention from others (Kose et al. 2018; Neil and Sturmey 2014; Vause et al. 2018). Given the acknowledged difficulty in differentiating between OCD symptoms and higher-order RRBs, the term obsessive-compulsive behavior (OCB) has been used by researchers to represent both phenomena (e.g., Chok and Harper 2016; Vause et al. 2018).

Given the early focus and popularity of using CBT to treat externalizing behaviors such as impulsivity, CBT for internalizing issues such as anxiety is considered the “second generation for CBT” (Kendall and Choudhury 2003, p. 89). Although CBT consists of a multitude of components, keystone strategies typically involve (a) cognitive training with an emphasis on cognitive restructuring techniques; (b) using behavioral principles to foster skill development with use of reinforcement; and (c) exposure-based strategies (Scarpa and Lorenzi 2013). Regarding pediatric anxiety and OCD, the two first-line treatments include CBT with exposure-based therapy and pharmacological treatment including selective serotonin reuptake inhibitors [SSRIs] (Rosa-Alcázar et al. 2015; Sánchez-Meca et al. 2014; Schwartz et al. 2019; Torp et al. 2015). With

18 studies that met their inclusion criteria, a meta-analysis conducted by Sánchez-Meca et al. (2014) for pediatric OCD examined the differential efficacy of treatments and showed a reduction in symptoms with a large effect size for CBT alone and CBT with pharmacological treatment, with effect sizes being significantly higher than pharmacological treatment alone.

Regarding the pediatric ASD population, randomized controlled trials (RCTs) evaluating treatment of anxiety disorders in children and youth with ASD have established the efficacy of CBT with cognitive, linguistic, and ASD-specific adaptations (e.g., social skills modules; Wood et al. 2009) to meet the needs of this population (Sukhodolsky et al. 2013). However, these studies focused on anxiety disorders (DSM-5; APA 2013), including a very small sampling of individuals with a primary diagnosis of OCD (which is now part of obsessive-compulsive and related disorders in DSM-5, APA 2013). Promisingly, in the last 15 years, there has been increased interest in evaluating psychosocial treatments for OCB in ASD. Limited research still exists regarding the use of pharmacological treatment such as SSRIs for anxiety disorders and OCD in the ASD population, and preliminary evidence suggests possible side effects such as impulsivity (Postorino et al. 2017). The present summary will cover (i) the current state of knowledge on CBT interventions for OCB with an emphasis on adaptations for this unique population, (ii) behavior analytic interventions based on functional behavior assessment to address OCBs, and, finally, (iii) the blending of adapted CBT with function-based behavior assessment and behavior analytic components for children and youth with ASD. Future directions will be discussed.

Current Knowledge

A series of CBT case studies follow a general CBT protocol for pediatric OCD developed by March and Mulle (1998) and other CBT experts. The main ingredient is exposure and response prevention (E/RP), where a youth is exposed to the internal and external stimuli associated with

anxiety and refrains from engaging in the compulsion resulting in habituation in the presence of those stimuli. E/RP along with traditional components such as psychoeducation and “bossing back OCD,” creating a hierarchy of least-to-most anxiety-provoking OCD symptoms, and teaching cognitive and behavioral skills were largely adapted from the work of March and Mulle. Tailoring the treatment to children and youth with high-functioning ASD, a number of case studies (e.g., Elliott and Fitzsimons 2014; Lehmkuhl et al. 2008; Reaven and Hepburn 2003) demonstrated clinically significant reductions in reported symptoms. Varied modifications were used to tailor treatment to each child or youth to meet his/her idiosyncratic needs. Specifically, emphasis was placed on adaptations such as increased use of visual stimuli, individualized story metaphors, self-monitoring of behavior, use of positive reinforcement such as verbal praise, a simplified cognitive component, and increased parent involvement (Kose et al. 2018).

Two studies compared a standard CBT protocol for OCBs in children and youth with and without ASD. One study used an open trial to compare standard group CBT for youth with OCD alone ($n = 23$) versus OCD and ASD [$n = 15$] (Farrell et al. 2012). Using the CY-BOCS (Goodman et al. 1986), the standard group CBT protocol showed that the protocol was equally effective for participants with and without ASD. In contrast, using similar outcome measures, a subsequent trial involving a case-controlled comparison (n 's = 22) indicated that standard CBT treatment was less effective for youth with ASD and OCD in comparison to when OCD was the sole diagnosis (Murray et al. 2015). Treating both anxiety disorders and OCBs in children and youth with ASD suggests that several adaptations are likely necessary to maximize CBT treatment success for this underserved population.

In addition to CBT studies, selected studies have used single-case experimental designs to illustrate the success of interventions based on behavior analytic principles to reduce OCBs in children and youth with ASD, including functional behavior assessment procedures. In these

studies, all participants had a diagnosis of ASD with an accompanying intellectual disability (ID). Behavior analysis is predicated on the understanding of motivating factors and environmental contingencies that maintain these learned behaviors. To date, a wealth of research provides empirical support for the use of functional behavior assessment methods to guide intervention decisions regarding behavior reduction and adaptive skill development in individuals with ASD and related disabilities (Hanley et al. 2003; Matson and Williams 2014; Mulligan et al. 2014). Although individuals with ASD may engage in compulsive behaviors to eliminate anxiety and distress, there may be additional factors operating such as a deprivation of attention from others (especially given challenges in social-communicative skills), seeking sensory stimulation to modulate arousal, or a need to escape an undesired task (Martin and Pear 2019; Vause et al. 2017). By assessing all possible variables that may be maintaining a particular behavior, an individualized comprehensive treatment plan can be devised.

Regarding OCBs, a small number of studies have used a wide variety of antecedent and consequent interventions to treat compulsive behaviors in children and youth with ASD and ID including ordering and arranging (e.g., Chok and Harper 2016; Rodriguez et al. 2012); rigid routines (Rispoli et al. 2014); and throwing away non-trash stimuli (Kuhn et al. 2009). For example, in a study by Rodriguez et al. (2012), a functional analysis was employed for one ordering and arranging behavior in each of three youth (13 to 15 years) with ASD and ID and revealed automatic positive (sensory) reinforcement as the maintaining variable. Intervention included access to competing stimuli combined with response blocking and, in one case, product extinction (returning furniture to its original position) that led to a reduction of OCBs to near-zero levels. In a different study, using a latency functional analysis with heart rate monitoring, Chok and Harper (2016) indicated automatic positive reinforcement as the maintaining variable for arranging items in a 12-year-old female with ASD, febrile seizures, and limited communication skills. Using a multiple schedule design, a

discrimination training procedure effectively addressed this compulsive behavior. Using the Chambless and Hollon (1998) criterion for empirically supported treatment, based on four single-case research designs including six participants conducted by four independent research teams, Neil and Sturmey (2014) reported that behavior analysis and behavior modification met criteria for *probably efficacious treatment* for OCBs in children with ASD. Targeting a wide range of OCBs including need to touch rituals, symmetry and exactness, repetitive questioning, and bathroom-related rituals, behavior analytic treatment included procedures such as functional communication training, differential reinforcement, token economies, response blocking, fading, and extinction.

Overall, CBT case studies with varying adaptations for children and youth with high-functioning ASD showed promising results in reducing OCBs, and nonrandomized group studies employing a standard CBT protocol showed mixed results. Single-case experimental designs evaluating assessment and treatment derived from ABA (including functional behavior assessment) have been successful in reducing OCBs in children and youth with ASD and ID. With increasingly rigorous research designs, the *combination* of adapted CBT and ABA elements (e.g., positive reinforcement, functional communication training) derived from functional behavior assessment methods has been explored.

A small number of case studies and single-case experimental designs have evaluated this combined approach (e.g., Boyd et al. 2013; Chok and Koesler 2014; Neil et al. 2017; Vause et al. 2014) with children and youth with ASD. With an emphasis on E/RP and behavior procedures, Boyd et al. (2013) attempted to lessen OCBs in 5- to 11-year-old children with ASD and ID. Using exposure trials and redirection to alternative tasks, Boyd and colleagues showed mixed results with some participants showing a marked change in duration and latency to engage in a respective OCB. In a study by Chok and Koesler (2014), a functional analysis was used with a 14-year-old male with ASD and severe ID for excessive cleaning behavior. In this case, functional analysis

results showed differing measures of heart rate when access to wiping was allowed versus when it was restricted. It was reported that when E/RP with response blocking was implemented, rates of cleaning reduced to near-zero levels.

Using a multi-component CBT with inclusion of functional behavior assessment, a small pilot group design (Vause et al. 2017) tested a manualized group functional behavior-based CBT (Fb-CBT) entitled *I Believe in Me, Not OCB!* (Vause et al. 2013) with children with high-functioning ASD. This manual built on the work of March and Mulle (1998) and other CBT experts (Piacentini et al. 2007a). Fourteen children with ASD ranged in age from 8 to 12 years, with seven children randomly assigned to the experimental condition and seven children to treatment as usual (TAU). Participants assigned to TAU continued with any services that they were currently accessing. Two primary outcome measures including the RBS-R (Bodfish et al. 1999) and the five-item compulsion subscale of the CY-BOCS (Goodman et al. 1986) demonstrated that this multimodal Fb-CBT treatment (e.g., psychoeducation, cognitive and behavioral skills training, and E/RP) with ABA components (including functional behavior assessment) significantly decreased OCBs at posttreatment, and results were maintained at 5-month follow-up, with medium to large effect sizes.

Vause et al. (2018), the first known RCT to treat OCBs in children and youth with high-functioning ASD, included 37 children (7–13 years) who were randomly assigned to the experimental group ($n = 19$) or TAU ($n = 18$). For those in the treatment condition, based on the extent of interference and distress in the youth's life and impact on family functioning, several OCBs were chosen and treated per participant over a 9-week period. Fb-CBT consisted of group-based activities, work in parent-child dyads, and parent coaching. Children were treated in small groups consisting of three or four children (with at least one parent) and two experienced therapists. Similar to CBT studies tailored to ASD, to maintain interest in the program, sustain attention, and foster comprehension skills, several adaptations were embedded including a

predetermined program plan with frequent repetition, presentation of material in various modalities (e.g., visual stimuli paired with auditory; 3D vs. 2D materials), incorporation of immediate and delayed reinforcers, inclusion of circumscribed interests, and hierarchically determined social skills exercises (e.g., greetings with fellow participants which progressed to playing interactive games).

The treatment program was comprised of two phases. The first phase (2.5 sessions) involved psychoeducation and mapping of *all* OCBs. This general phase focused on rapport building, psychoeducation about "OCB," operationally defining compulsions (and related obsessions when present) as well as triggers, using a fear thermometer to visually map out compulsions and determine a child's perceived control in resisting OCB (or performance of the compulsion), and creating externalizing statements (e.g., "Buzz off, OCB!"). Extending beyond discussing OCBs, similar to Reaven and Hepburn (2003), various concepts were introduced such as interference caused by obsessions and performing compulsions, and how these behaviors may impact the quality of life for the youth and his/her family members.

Following this general framework, in session 3, *individualized* work began for each compulsion in a graded fashion or based on a least-to-most hierarchy (March and Mulle 1998). Beginning in session 3, behavior analytic-based individualized treatment for each OCB was initiated with a functional behavior assessment to identify singular and multiple perceived functions of the targeted compulsive behaviors. For each OCB, an indirect assessment called the Questions About Behavior Function (QABF; Matson and Vollmer 1995) was used. The QABF is a parent rating questionnaire that shows good psychometric properties for the ASD population (Matson et al. 2012) and attempts to address functions including attention, nonsocial, tangible, and escape as well as physical pain/discomfort as an antecedent event. This assessment measure was supplemented with descriptive data conducted by a researcher trained in behavior analysis to analyze antecedents and consequences of perceived functions pertaining to each OCB.

Using these assessment methods in combination, a function-based assessment and intervention plan (FBAI) was derived to accompany the CBT approach.

The FBAI helped to identify alternative replacement skills that served the same function as the OCB. For example, consider an identified perceived function (beyond anxiety reduction) of “needing to tell” on siblings as social attention. In replacement of attending to the “need to tell” behavior, a parent was coached to minimize conversation around the telling behavior and to teach alternative behaviors such as conversational skills with prompts, social stories, or social script fading. Throughout this phase, participants learned key behavioral skills (e.g., functional communication, relaxation) that were appropriate to the targeted OCB and could also be generalized to other compulsions and different settings. Cognitive training existed on a spectrum where cognitive restructuring was attempted with a variety of modalities (e.g., verbally reframing thoughts, gathering facts, using visual representations to explain concepts) but like previous research (e.g., Lehmkuhl et al. 2008) was modified as needed based on the cognitive, linguistic, and interpersonal needs of the child. If there was an absence of a thought/obsession, focus was on simplified statements such as “I’m OK” or “I can beat this” (with engagement in an alternative behavior such as choosing a preferred activity or engaging in social conversation). Utilization of CBT skills training was encouraged when engaging in graded E/RP both in session and at home with positive reinforcement such as verbal praise and tangibles. Each of the nine sessions consisted of 30 min of parent coaching where parents learned the key concepts and procedures. Following parent coaching, they attempted to work with their child as independently as possible, with a therapist present to assist as needed.

Regarding general outcomes for this RCT evaluating the Fb-CBT treatment package for children and youth, the two primary outcome measures including the RBS (Bodfish et al. 1999) and the CY-BOCS compulsion subscale (Goodman et al. 1986) showed statistically significant differences between the experimental group and TAU with

large effect sizes, and these results were maintained at 6 months (Vause et al. 2018). Of note is that multiple OCBs were treated for each child ranging from 3 to 9 compulsions ($M = 6$). Secondary measures also examined level of functional impairment (e.g., Child Obsessive-Compulsive Impact Scale-Revised; Piacentini et al. 2007b) with the experimental group faring significantly better than TAU, and parents were generally satisfied with the treatment which supports the social validity of Fb-CBT.

The summarized literature demonstrates that using adapted CBT shows promise in successfully treating OCBs in children and youth with ASD. Combining adapted CBT with the discipline of ABA and, specifically, inclusion of functional behavior assessment may provide a more comprehensive clinical picture that aids in maximizing the reduction of OCBs and improving quality of life for individuals and their families.

Future Directions

Regarding assessment and treatment of OCBs in children and youth with ASD, there are several areas that require further attention and exploration. First, standardized assessment tools that are normed for an ASD pediatric population need to be developed. Whether used diagnostically or as a means of determining severity and interference of OCBs, given the acknowledged lack of introspection and often limited vocal communication in children and youth with ASD, future research may examine simplifying existing standardized interviews or combining interview questions with direct and/or self-observation, where possible.

In the RCT study (Vause et al. 2018), an indirect assessment with analysis of descriptive observational (antecedent-behavior-consequence) data was collectively used to determine perceived functions of OCBs. Through experimental manipulation of variables, functional analysis targets behavioral functions (Cooper et al. 2019). However, when treating multiple OCBs, it may be impractical to conduct multiple functional analyses per participant, and given the covert nature

of obsessions, experimental conditions may be difficult to design and repeatedly implement. However, future research may examine brief functional analyses and the use of physiological measures such as heart rate monitoring (Chok and Koesler 2014).

Although studies report promising results, additional randomized controlled trials are sorely needed to firmly establish the efficacy of adapted CBT alone as well as the additive value of combining CBT with ABA-based procedures including functional behavior assessment for children and youth. Addressing *all* maintaining variables in a treatment package derived from function-based assessment may quicken treatment response for OCBs. Typically, CBT studies included high-functioning individuals, whereas ABA studies included children and youth with ASD and an ID. Future research is needed with children and youth who present with a wide range of cognitive and adaptive levels to evaluate ideal treatment modalities, including psychosocial and pharmacological treatment. Research is needed to tease out key treatment components that are evidence-based for varying populations. Studies involving component analyses may aid in determining active ingredients for a range of ASD presentations, including children with ASD alone as well as those presenting with comorbid conditions such as attention deficit hyperactivity disorder (ADHD), comorbid anxiety, and varying neurodevelopmental disorders (DSM-5, APA 2013; Postorino et al. 2017). Also, examination of sociocultural variables (e.g., socioeconomic status, cultural values) is crucial in designing treatment protocols that are person- and family-centered to meet the needs of youth and their families.

Evaluation of CBT and combined treatments is also needed across varying age ranges. For example, only a handful of case studies and one RCT (Russell et al. 2013) have evaluated CBT to treat OCBs in older adolescent and adult populations with ASD. In this study, 46 adolescents and adults with a mean age of 27 years were randomized to CBT versus an anxiety management condition, with both groups showing significant reductions in OCBs. Extension is also needed to younger populations, with an emphasis on early

intervention for children of preschool age presenting with ASD and other related disabilities (Guertin et al. 2019).

To date, published research shows promise, but as suggested above, additional research evaluating singular and dual treatment modalities including Fb-CBT, with consideration of variables including level of cognitive functioning, comorbid presentations, cultural factors, and various age ranges, is needed. A focus of future studies should be on the establishment of a strong evidence base for treating obsessive-compulsive behavior with manualized packages such as Fb-CBT that are tailored to the needs of individuals across the ASD spectrum.

Functional Communication Training

Patricia Prelock

Communication Sciences and Disorders, Dean's Office, College of Nursing and Health Sciences, Burlington, VT, USA

Definition

Functional communication training (FCT) is a systematic approach to intervention in which a more socially appropriate behavior is taught to replace a challenging behavior (Durand 1990; Durand and Merges 2008, 2009; Prelock et al. 2011). It is presumed that the challenging behavior is an attempt to communicate; therefore, vocalizations, manual signs and gestures, or graphic symbols are used to replace the less desirable behaviors. Notably, FCT is used in combination with other interventions (Durand 1999; Olive et al. 2008).

Historical Background

Challenging behavior is a frequent occurrence for individuals with ASD, particularly when they do not possess the speech and language skills required to communicate their wants and needs. These behaviors may include self-injury, tantrums, aggression, etc. Research suggests that individuals with disabilities, and particularly those with ASD, are more likely to exhibit problem behaviors that are frequent, severe, and sustained over time. These behaviors interfere with family life and make it difficult for individuals with ASD to be integrated in their community. Further, such behavior problems are a strong predictor of school failure (Feldman et al. 2007). Therefore, behavioral strategies have been established to address these behavior problems. Durand, Carr, Dunlap, and colleagues recognized that these challenging behaviors are often a result of an inability to communicate intent including an

individual's wants, needs, and desires (Carr and Durand 1985; Dunlap et al. 1991; Durand 1990; Durand and Merges 2008, 2009). FCT was designed as an intervention technique to address the reported challenging behaviors in individuals with ASD and other developmental disabilities by replacing the undesired behaviors with an alternative that is based on the perceived and assessed intent of the behavior. A variety of professionals (e.g., psychologists, speech-language pathologists, behavioral interventionists) and families use FCT across age, language skills, and developmental abilities in several contexts (Dunlap et al. 2006; Durand 1999; Mancil 2006; Petscher et al. 2009). FCT has strong support in the literature as an established skill-based intervention (Smith et al. 2007).

Rationale or Underlying Theory

There are several concepts that provide a theoretical framework for understanding why FCT is an effective intervention for reducing challenging behavior. Three concepts have been identified as crucial to understanding FCT and implementing it with a diverse population: functional equivalence, natural communities of reinforcement, and features of the alternative response (Carr 1988; Durand 1987, 1990, 2012; Durand and Merges 2009).

Functional equivalence is used to explain how and why behavior changes in FCT. Assumptions are made about why a behavior occurs such as being reinforced by getting the attention of another or escaping from doing something. If this is true, then these challenging behaviors could be adjusted by offering an alternative or new behavior that achieves the same function. Thus, FCT reduces problem behavior because it involves teaching and reinforcing a replacement behavior that serves the same function.

Using a communication strategy as a replacement for challenging behavior has an added advantage of being able to capitalize on "natural communities of reinforcement" (Durand 1990). This means an individual learns to ask for a reinforcer from a variety of communication partners,

and those partners do not require specific training from an interventionist.

A third component underlying the conceptual framework of FCT that is important to the success of this intervention is the opportunity for creating an alternative response (Durand and Merges 2009). An alternative response is one that is functionally equivalent to the challenging behavior and includes several features like how closely it matches the function of the behavior, how successful and efficient it is likely to be, how recognizable and acceptable it is as a response, and how it works in the natural environment (Durand 2012).

An important principle in understanding the approach and value of FCT is that behavior problems are not viewed as undesirable occurrences that must be eliminated. Instead, challenging behaviors are viewed as functionally equivalent to other modes of communication. This view recognizes that although the behaviors may be unacceptable, what is being communicated is not (e.g., getting attention, asking for help). This is a critical concept because the intervention goal changes. Instead of eliminating the behavior and providing no alternative for accessing what an individual needs or wants, an alternative and more acceptable communication behavior is taught so the desired reinforcer can be achieved.

Goals and Objectives

FCT is primarily designed to address a range of challenging behaviors that interfere with an individual's ability to fully participate in learning, and family and community life. In fact, parental stress is known to increase when parents are dealing with a child exhibiting challenging behaviors (Floyd and Gallagher 1997; Hastings 2002; Saloviita et al. 2003). Appropriate targets may include self-injury, aggression, tantruming, stereotypies, and inappropriate sexual behavior, to name a few (Fyffe et al. 2004).

Treatment Participants

FCT can be implemented for anyone who displays problematic behavior. It is an appropriate strategy

to address the behavior challenges reported for individuals with ASD as well as other disorders (e.g., ADHD, schizophrenia, traumatic brain injury) in which behavior problems are a frequent occurrence (Durand and Merges 2009). Research also suggests that FCT can be used to address the difficult behaviors of individuals of all ages with a range of language and cognitive abilities (Bird et al. 1989; Mancil 2006; Petscher et al. 2009).

Treatment Procedures

FCT requires the implementation of three primary steps: (1) assessing the function of the challenging behavior to be addressed, (2) selecting an appropriate alternative to the challenging behaviors, and (3) teaching the alternative response and fading prompts to use the alternative response in the environment.

To begin FCT, the interventionist identifies the antecedents (what comes before) and consequences (what follows) of a problem behavior in an effort to assess the function the behavior serves. When the function is determined, individuals are taught to make a request in a more acceptable manner. Selecting an alternative communication modality to make this request is a critical next step. Consideration is given to those modes of communication the individual has already demonstrated some skill (e.g., signing, graphic symbols, writing, verbalization).

Once an alternative mode of communication is identified, teaching situations are created. First, the environment is arranged to provide multiple opportunities for using the new communication strategy. Situations are established that are most likely to elicit the interest of the individual. Training opportunities are interspersed through the day in the environment where the individual is expected to communicate. This approach increases the likelihood of intervention effects that are generalized and maintained.

Several language training techniques are required to teach individuals to communicate their intent using an acceptable means as a replacement for their challenging behavior (Durand et al. 1999). Prompts are used to teach

the new response and then are faded as quickly as possible. Prompts may be full physical prompts or partial physical, gestural, or verbal prompts. Delayed prompting is also used to help fade the prompting and encourage spontaneous use of the desired communication behavior (Halle et al. 1981; Schwartz et al. 1989). Once an individual demonstrates success in using the new communicative behavior in three of five consecutive opportunities, prompt fading begins to eliminate prompt dependency.

The context for training occurs on a continuum from more artificial settings like a therapy room to more natural settings like the community. The context is largely dependent on where the individual is expected to use the new trained communication response. If training begins in a more restricted setting like a therapy room, once the response is learned, performance should be encouraged in the settings where the behavior is expected to occur to ensure generalization and maintenance.

Efficacy Information

There are more than 200 studies documenting the effectiveness of FCT for addressing challenging behaviors for a range of individuals (Durand and Merges 2008, 2009; Mancil 2006; Mirenda 1997; Petscher et al. 2009). Research also suggests that FCT successfully decreases problematic behavior and increases communication in individuals with ASD. Some of the communicative responses that have been successfully taught as a replacement to difficult behaviors include mands (O'Neill and Sweetland-Baker 2001) and augmentative and alternative communication (AAC) strategies such as signing, communication books, and voice output devices (Mirenda 1997). The use of these replacement behaviors has led to increased spontaneous and appropriate verbal communication (Mancil 2006) that is maintained and generalized to untrained activities (Olive et al. 2008; Wacker et al. 2005).

Petscher et al. (2009) reviewed over 80 studies describing FCT as a treatment to address problematic behaviors and found it met their

preestablished criteria for a well-established intervention. This supports the findings of the National Standards Project (2009) which also identified FCT as an established behavioral intervention that has successfully decreased problem behaviors, restricted repetitive behaviors, and increased academic, communication, and social behaviors in individuals with autistic disorder and pervasive developmental disorder – not otherwise specified ranging in age from very young to 21 years.

Although there is extensive research examining the effectiveness of FCT, most studies use single-subject designs with small numbers of participants. Some larger studies do exist (e.g., Durand and Carr 1992; Wacker et al. 1998), but no randomized clinical trials have been reported that compare treatments or outcomes to no treatment.

Durand and Rost (2005) suggest that there is some question about the representativeness of the literature examining behavioral interventions including FCT. They suggest it is unclear if the current intervention research systematically excludes certain individuals which would influence the results and applications to specific populations.

Outcome Measurement

Functional behavioral assessment (FBA) is a key element in the implementation of FCT (Durand 1990). FBA is used to determine the function of problematic behavior that eventually leads to selecting a more appropriate alternative communication behavior. The selection of the alternative behavior must serve the same function as the challenging behavior.

Informal observations, antecedent-behavior-consequence (ABC) charts, functional analyses, and a variety of rating scales are frequently used to determine the function of a behavior. Functional analysis is often identified as the best method to determine the function of a behavior. It is a process by which aspects of the environment are manipulated to assess behavior change (Hanley et al. 2003), although there are challenges in gaining accessibility to manipulate the

environment. There are also some influences that may not be conducive to manipulation.

Assessment typically begins with interviews of those who know the individual best as well as informal observations. Once this information is gathered, more formal assessments are completed to validate the impressions made from the informal assessment. Available instruments include the *Motivation Assessment Scale*, the *Motivation Analysis Rating Scale*, the *Functional Analysis Interview Form*, the *Functional Assessment Checklist*, the *Functional Analysis Checklist*, and the *Questions About Behavioral Function*.

Data collection requires establishing goals, analyzing behavior patterns, assessing environmental obstacles, and monitoring results (Durand and Hieneman 2008a, b). To establish goals, there needs to be sufficient information to define the problem and determine the desired responses across settings. Different forms of functional assessment are then employed to analyze behavior patterns. The learning environment is then examined to identify what alternative communicative responses could be supported. Those responsible for collecting data are then identified and trained to tally responses (Durand and Hieneman 2008a, b).

Qualifications of Treatment Providers

Individuals who implement FCT are usually highly trained in behavioral strategies and recognize the role of behavior in communication. FCT is best implemented using a team approach in collaboration with a psychologist who has experience with functional behavior assessment and a speech-language pathologist who can help to identify the function and appropriate replacements for expressing communicative intent considering an individual's cognitive and communication abilities. Children with ASD often require a behavioral plan, so once this is developed, training needs to occur for all those who come into contact with the individual who is exhibiting challenging behavior. Adequate training in behavioral principles is necessary to ensure that regression does not occur and behavior problems do not increase (Durand and Carr 1991, 1992).

Functional Ecological Approach

Robert H. LaRue

Douglass Developmental Disabilities Center,
Rutgers, The State University of New Jersey,
New Brunswick, NJ, USA

Definition

The functional ecological approach is an approach to the assessment and intervention process that emphasizes environmental variables that may contribute to target behavior (Powers 2005, 1997). The model stands in contrast to earlier conceptualizations of behavioral assessment focusing on the topographical aspects of behavior (i.e., what the behavior looks like) rather than focusing on the underlying function (or cause) maintaining behavior. In contrast, the functional ecological emphasizes the need to evaluate the individual's behavior in a broad developmental context, accounting for relevant antecedent and consequent conditions affecting behavior.

The process emphasizes the context in which behavior occurs, thus increasing the likelihood that the assessment process, intervention strategies, and outcomes lead to benefits across environments. The approach leads to (1) the modification of the environment in which the target behavior occurs, (2) the manipulation of the controlling contingencies fort target behavior, (3) the development of functional equivalent replacement skills, and (4) the development of functional and socially valid skill repertoires. These gains exert their effects in multiple settings and are maintained in the natural environment.

Functional Goals

Shaunessy Egan

Center for Children with Special Needs,
Glastonbury, CT, USA

Definition

A functional goal outlines a target skill to be acquired in measurable terms, while including a precise behavior to be accomplished and a specific criterion. It identifies the behavior or skill caregivers/instructors want the individual to learn or accomplish, the context in which the skill will be taught, and a quantifiable level of mastery. Functional goals should be developed so that they are implemented and practiced within the individual's daily routine.

Functional goals include three components: an acquisition statement, a normalized context, and a criterion. An acquisition statement describes the target behavior in terms that are observable and measurable. A normalized context identifies the activities or daily routines in which the behavior is expected. A criterion states the desired level of the behavior for mastery of the skill.

- If the student is unable to perform the skill himself or herself, it would need to be completed by another person.
- The skill will be needed throughout the person's life.

Historical Background

The philosophy behind teaching functional life skills is full inclusion in all activities of family and community life, making adaptations where necessary. There is one absolute purpose of education for all students, including those with autism spectrum disorder (ASD): Preparation for adulthood. The Individuals with Disabilities Education Act (IDEA 2004) was established to ensure all children with disabilities reach this collective goal and are provided opportunities for acquisition of knowledge and skills that lead to personal independence and social responsibility.

Research on the outcomes of adults with ASD yields sobering results. While some individuals with ASD are able to successfully achieve maximum independence and live self-fulfilling lives, many are faced with very significant obstacles in multiple areas. Even for those considered to be more skilled, they are unable to negotiate their way into college, work, community participation, and independent living. Experience has proven that individuals with all levels of ASD can work in a variety of businesses and industries (McDonough and Revell 2010; O'Brien and Daggett 2006). A spectrum of employment options is now available which includes segregated training centers, supported employment, and competitive employment. Despite research documenting the benefit of community-based employment, the vast majority of people with ASD continue to be unemployed or underemployed (National Organization on Disability 2004; Taylor and Seltzer 2011; Wagner et al. 2005). Additionally, participation in secondary education may provide a suitable alternative to employment; however, limited research in this area indicates participation is low (Howlin 2000). There is a continuum of living arrangements available to individuals with ASD which

Functional Life Skills

Dawn Hendricks

Department of Special Education and Disability Policy, VCU Autism Center for Excellence, Virginia Commonwealth University, Richmond, VA, USA

Definition

Functional life skills are the variety of skills which are frequently demanded in natural domestic, vocational, and community environments. The skills involve those immediately applicable to daily life or may also include those which teach students to participate in future environments (Brown et al. 1979). Key qualities of functional skills include the following:

- It is performed within the context of a real activity.
- The activity is meaningful to the student.
- People without disabilities believe the activity serves a purpose.

includes living independently, living with family, partially supported living, and fully supported living. While an array of residential options is available, research on living outcomes demonstrate a small percentage of adults with ASD live alone, some reside in long stay hospitals or institutions, but most continue to live at home with their parents (Billstedt et al. 2005).

Such disappointing outcomes for adults with ASD have led to a shift in ensuring functional life skills are addressed during the educational years. Although it is important to focus on academic content and ensure students with ASD are provided the opportunity to benefit from the general education curriculum, it is also necessary to ensure they are taught skills needed to achieve independence and community integration. This should not be viewed as a lessening of goals but instead as an opportunity to engage all students in real-life application of skills.

Current Knowledge

Each student is an individual and requires a specialized set of learning objectives specifically designed to meet his or her needs. In many classrooms across the United States, students' individualized education plans (IEP) are virtually identical in content. This is providing an injustice to many students, as not all will require the same skills to achieve maximum independence. Considerations regarding functional life skills designed for current and future success will include different learning objectives based on the student. Such skills are individualized and focus on the unique qualities, dreams, and desires of the student. They require planning for the future, providing a positive road map regarding what it may hold, and systematically addressing the skills needed to achieve it. Through such visionary planning, the student learns what is needed for enhanced functioning in the natural community.

Determining skills to teach involves cooperation between students and teachers. Perhaps the most important factor when selecting functional life skills to teach is the value of student

and family preferences. Of crucial significance is whether the student is interested in the skill and has had a role in selecting the objective. If the student has been involved, he or she will be more motivated to learn it and is far more likely to use it outside of the school setting. Additionally, learning skills the student is vested in can lead to increasing self-concept and sense of accomplishment.

Another critical step to determining functional life skills requires examining a student's current and future environments (Brown et al. 1976). An ecologically oriented approach requires the student, teacher, and family to identify the environments and sub-environments where the student participates. For example, the student may participate in the school, home, synagogue, gym, and park. Next, the team discusses the student's high-priority activities for each of these major living environments. For example, if the student goes to a fast-food restaurant every Saturday, he may need to learn to take turns, wait, order food, and exchange money. There is no limit to the number of functional life skills identified using an ecological approach since any student with an autism spectrum disorder will have some deficits related to increasing independence that will need to be addressed (Schall et al. 2012).

Although targeting functional life skills is traditionally emphasized at the high school level, they should be carefully considered for elementary and middle school students as well. Certainly, as the student ages and needs to evolve, the skill requiring instruction will change. Acquisition becomes more essential as the student gets closer to graduation but should begin early for every student with ASD.

Although functional life skills will differ from individual to individual, there are key areas to be addressed. They include the following:

- Career education and work: Students need to learn skills that will allow them to identify a career path, obtain and hold a job, and understand the relationship between work responsibility, pay, and getting along with others (McDonough and Revell 2010; Wehman 2001).

- **Community participation:** Community-based skills encompass a breadth of skills related to mobility, accessibility, and interactions. Listing the number of skills related to community is nearly impossible because there are so many. However, skills may include using a sidewalk, crossing a street, soliciting a retailer, or waiting in line at a movie theatre.
- **Home living skills:** Domestic skills are essential for community living. The optimal living environment for the student must be identified and then the skills essential for success targeted. Examples of home living skills include preparing lunch, cleaning the bathroom, and making the bed.
- **Self-help:** A key component of independence is self-care. Self-help skills allow a person to meet his own needs and be less reliant on another person. Self-help skills include such skills as eating, meal preparation, dressing, grooming, and toileting. They are critical skills as some are needed to survive (e.g., eating), while others are needed to leave the house and participate in the community (e.g., getting dressed). Self-help skills can be a major factor in accessibility to certain environments. For example, a young child with ASD who is not toilet trained may not be allowed in a child care center, while an adult with ASD who cannot use a public restroom may not be able to maintain a job.
- **Transportation:** A major aspect of independence in the community is related to getting to and from various locations. Skills related to transportation include not only using various modes of transportation such as driving a car or using a bus but also include planning travel based on desire as well as need to get to determined locations.
- **Self-determination:** Self-determination prepares students for adulthood teaching them to take control over their lives, understand their rights, and self-advocate. Too often, students with ASD become highly dependent on caretakers. This reliance then inhibits independence. Some examples of skills related to self-determination include self-awareness, goal setting, choice making, decision-making, assertiveness, and problem solving (Wehmeyer and Lawrence 1995).
- **Personal health and safety:** Acting responsibly and promoting the well-being of one's self as well as others is a vital functional skill. This focuses on attending to one's own health needs and demonstrating behaviors that ensure safety and may include such skills as applying a Band-Aid, calling 911, or monitoring medication.
- **Financial planning and management:** Economic self-sufficiency is a goal for most individuals with or without a disability. Activities may range from basic skills such as managing money to more complex activities including investment planning. Skill related to financial planning involves knowing how to shop by comparing prices, budgeting, saving for a purpose, investing, as well as avoiding scams and unfair marketing practices.
- **Functional academics:** Most education programs focus on academic content. For some students, learning the general education academic curriculum may not be possible. Therefore, functional academics may be advantageous. This involves teaching academic content in a way that uses real-life application and moves the student toward independence. For example, a student working on reading may learn to identify sight words he or she will see in the community. A student working on math may learn to count money and add the cost of two items purchased. An essential way to determine whether to teach functional academics is to ask whether the student will be able to use the information currently or in the future or if the information is needed to obtain the student's educational goals. Increased learning of functional academics may impact the type of diploma received and may determine whether the student is able to pursue postsecondary education.
- **Socialization:** Appropriate social skills are essential for all people. Socialization deficits is the hallmark characteristic of ASD. Therefore, targeted instruction in this area is required for every student on the spectrum. The skills required for socialization are complex and are

arguably the most difficult for an individual with ASD to learn. However, unless social skills are taught, full community integration and social fulfillment remain a challenge (National Research Council 2001). Socialization skills include those related to peer interaction, friendships, and the range of relationships one may encounter. Additionally, socialization includes skills related to comprehending social stimuli, reciprocation, social rules, and affect and emotions.

- Sexuality: Sexuality is a natural part of the human experience, and it is a right for individuals with ASD to experience it. Skills related to understanding the facts regarding sexuality as well as the social rules surrounding its expression are typically required for a person on the spectrum (Stokes et al. 2007).
- Recreation and leisure: Students need to learn activities to perform in his or her free time. For many with ASD, leisure pursuits are rarely community based and are likely to be isolated activities such as video games and watching television (Jennes-Coussens et al. 2006; Wagner et al. 2005). Skills related to recreation and leisure may include teaching independent play skills to reduce stereotypy, interactive games, or team activities.

Future Directions

With the passage of No Child Left Behind (NCLB 2001) as well as the revision of IDEA (2004), access to the general education curriculum has become a more prominent focus for students with disabilities including those with ASD. However, as research has evolved and we have learned more about the autism spectrum, it has become increasingly clear that all students with this disorder require a focus on functional life skills in addition to other curricular content. Instruction is required related to community, employment, home, and leisure as well as academics related to the transition goals (Downing 2005; Nuehring and Sitlington 2003). Moreover, strategies for remedying communication,

socialization, and behavioral deficits which profoundly and perpetually impact the individual are critical (Iovannone et al. 2003). Future directions in this area include educating teachers on how to identify critical life skills students need to be successful as well as help them to integrate such skills into the general curriculum, so the student leaves school armed with the skills needed for adulthood.

Functional Magnetic Resonance Imaging

Devon Oosting¹ and Brent Vander Wyk²

¹Yale Child Study Center, Center for Translational Developmental Neuroscience, New Haven, CT, USA

²Yale Child Study Center, New Haven, CT, USA

Definition

Functional magnetic resonance imaging (fMRI) is a technique that examines brain activity by measuring blood oxygenation. When a region of the brain is in use, neuronal firing increases, and oxygen is supplied to that area by the blood. The oxygen-carrying protein in the blood, hemoglobin, is affected differently by magnetic fields based on whether or not the hemoglobin is oxygenated. This property allows us to index the relative amount of these types of hemoglobin in the blood, which is reflected in the **blood oxygen level-dependent (BOLD)** signal. A powerful magnet in the magnetic resonance imaging (MRI) scanner allows for the acquisition of data about where in the brain the BOLD signals are located. This signal tends to follow a particular activation pattern called the **hemodynamic response**. When neurons fire, oxygenated blood rushes to that area of the brain, displacing the deoxygenated blood about 2 s after firing, a response which peaks 4–6 s after the neural activation and then declines (see Fig. 1). This signal is an indirect measure of where in the brain activity is occurring, allowing for conclusions about which brain regions are active during certain cognitive processes.

Patients undergoing an fMRI scan lie still inside a tube, called a bore, with a coil placed above their heads. The head coil emits radio frequencies that, upon return, are captured by the coil in a manner proportional to the strength of the magnetic field there. The amount of energy returned depends on the degree of blood oxygenation, and the BOLD signal varies accordingly. The combination of a static magnetic field and oscillating gradient fields is used to create a

Functional Living Skills

► Assessment of Functional Living Skills (AFLS)

Functional Magnetic Resonance Imaging,

Fig. 1 The hemodynamic response

two-dimensional grid upon which the BOLD signal is localized.

Functional MRI is noninvasive and does not require the injection of a radioactive tracer, as do some neuroimaging approaches like positron emission tomography (PET) and single photon emission computed tomography (SPECT). fMRI has superior **spatial resolution** compared to other functional neuroimaging techniques, with the capability of locating brain activation in nearly any region within a few millimeters. Moreover, it has been used successfully with awake children as young as four (both typically and atypically developing), as well as with sleeping infants. However, fMRI exhibits limited temporal resolution due to the necessity of waiting to capture the BOLD signal's change and the technological limitations of whole-brain image acquisition, which occurs approximately every two seconds. Moreover, the signal itself is only a correlate of neural activity, not a direct measurement. fMRI is also expensive, with a single machine costing around 1.2 million. In order to do fMRI research, a highly trained team and dedicated space for the equipment are required, which adds to the total production cost.

Despite these challenges, fMRI provides insight into the neural mechanisms underlying a range of cognitive processes. In addition, fMRI can offer information on how brain activity differs between typically developing individuals and those with

intellectual, emotional, or developmental disabilities. fMRI findings can be examined in conjunction with data from other neuroimaging methods, such as PET, event-related potentials (ERP), magnetoencephalography (MEG), and functional near-infrared spectroscopy (fNIRS), all of which measure brain activity in different ways. Along with these other neuroimaging methods, fMRI can help to identify specific neurobiological indicators of disease and dysfunction toward the goals of prevention, early diagnosis, and individualized treatment.

Historical Background

fMRI Technology

Localization of BOLD responses with functional MRI is carried out in conjunction with a high-resolution structural MRI scan. The first structural image collected with MRI (a pair of water-filled test tubes) was published in 1973 and was created using four gradients oriented at different angles. This method was inefficient and time-consuming, which inspired the proposition of **echo-planar imaging (EPI)** in 1976. Echo-planar imaging uses rapidly shifting magnetic field gradients and a series of singular electromagnetic pulses to record MR signals. This approach dramatically decreased the time necessary to acquire an image and is the foundation of MRI technology used

today. The first magnetic resonance image of the human body was acquired in 1977, and by the late 1970s, medical personnel were beginning to realize the clinical potential of MRI. However, this early MRI technology could only reveal biological structure and was not sensitive to oxygen levels in the blood.

Throughout the next two decades, 1.5 T scanners were the most commonly used in research and clinical practice. Standard magnets were soon replaced with superconducting magnets, which made possible increases in the strength of the magnetic field (as measured in Teslas). When the Food and Drug Administration (FDA) approved MRI scanners for clinical use in 1985, their installation in hospitals increased dramatically, which facilitated greater interest in MRI and paved the way for functional MRI to flourish. Most MRI scanners used today are 3.0 T scanners, which appeared in the mid-2000s.

Blood Flow and the Hemodynamic Response

Early measurements of blood flow across the scalp were conducted in the 1890s by Angelo Mosso, a physiologist. He recorded pulsation on the skull during mental activity and provided some of the first evidence of the coupling of blood flow to neuronal activity. Though brain activity and blood flow had been linked repeatedly by the 1930s, there was not widespread acceptance of this idea as a way to measure brain function. PET was the primary method of neuroimaging for decades, despite the discovery by Pauling and Coryell of the differential reactions of oxygen-rich and oxygen-poor blood to magnetic fields in 1936. However, in 1990, Seiji Ogawa performed the first functional MRI scan measuring the BOLD signal in a rodent, which inspired the three studies published in 1992 examining the BOLD signal in humans. Since then, the number of studies using fMRI to examine changes in blood oxygenation as an indicator of brain activity has skyrocketed.

Current Knowledge

fMRI has been used to study the neural mechanisms underlying nearly every psychological

disorder, from depression and anxiety to schizophrenia and Alzheimer's disease, as well as many physical disorders. This broad use has resulted in a wealth of knowledge about the specific functionality of many areas of the human brain, information that can be used to augment our understanding of developmental disorders such as autism. The nature of fMRI is well suited to studying autism, as it can track brain structure and function during developmentally important periods. Current information points toward the causes of autism being, at least in part, neurobiological, making the examination of the structural and functional progression of the brain throughout disorder development crucial to understanding its etiology. Identification of where in the brain dysfunction is occurring also suggests potential areas for genetic or structural abnormalities, information that is unavailable from other imaging methods like ERP. Furthermore, unlike PET scans, which risk radioactive material accumulation and exposure when repeated too often, fMRI can be done repeatedly with minimal risk of ill effects. This allows for the longitudinal studies that are especially important for understanding the developmental trajectories of autism.

fMRI has been used to examine a number of processes thought to be relevant to autism-related behavioral symptomatology. One of the most highly studied networks of areas is the "social brain," which includes the orbitofrontal cortex (OFC), superior temporal sulcus (STS), amygdala, prefrontal cortex (PFC), and the fusiform gyrus (FG). These regions have been implicated in many socially related processes, such as face processing, detection and attention to biological motion, and theory of mind or thinking about the mental states of others.

For example, fMRI has revealed that individuals with autism tend to exhibit less activation in social brain regions when viewing biological motion, a phenomenon which is thought to be related to autistic deficits in attention to socially motivating stimuli such as faces. In support of this idea, adults with autism show significantly less activation in the FG, as well as activation in the superior temporal gyrus (STG), when viewing facial expressions. Moreover, adults with autism have been shown to utilize areas of the brain

Kaiser, M. D., Hudac, C. M., Shultz, S., Lee, S. M., Cheung, C., Berken, A. M., Pelphrey, K. A. (2010). Neural signatures of autism. Proceedings of the National Academy of Sciences, 107, 21223–21228)

associated with object feature processing (the inferior temporal gyrus) when processing faces, as opposed to using the FG as seen in typically developing controls. Taken together, these findings suggest that individuals with autism process faces differently than do typically developing individuals.

Research comparing the brain function of children with autism and their unaffected siblings against typically developing individuals is beginning to emerge. In one study, while viewing biological motion, children with autism showed

decreased activation in the PFC, STS, and FG as expected. However, their unaffected siblings, who were behaviorally indistinguishable from typically developing controls, also showed decreased activation in parts of the PFC and in the FG, likely reflecting the shared genetic vulnerability to developing autism. Unaffected siblings also exhibited unique patterns of activation in particular areas of the PFC and STS that were not activated in either affected or typically developing children (see Fig. 2). This activity could be a mechanism by which unaffected siblings

compensate for genetic vulnerability to autism or could reflect genetic factors that served a protective function against disorder development.

The existence of brain activation commonalities in children with autism and their siblings, and of compensatory activity in unaffected siblings, has been supported by other work. Decreased activation in the STS, FG, and PFC in response to happy faces was observed in both affected children and unaffected siblings compared to typically developing controls, indicating a potential common deficit in those at genetic risk for developing autism. Moreover, during a visual attention task, children with autism and their siblings both showed atypical, delayed activation in the frontocerebellar attention systems relative to controls, with the strongest activation in the unaffected siblings. This suggests that unaffected siblings are attempting to compensate for the delayed activation, which is likely a reflection of genetic vulnerability to autism.

Studies of this design offer a unique and powerful opportunity to identify **biomarkers**, neuroimaging findings exclusive to, or shared between, each subgroup (affected, unaffected, and typical). Accurate identification of these biomarkers can assist in developing an **endophenotype** of autism, which details the anatomical, neuropsychological, and physiological features that reflect genetic risk for developing the disorder. Current MRI work has highlighted potential anatomical biomarkers of autism risk, but the use of functional MRI to identify differences in brain activation is less prevalent. The identification of a reliable endophenotype of autism could provide important insight into the mechanisms underlying the disorder toward the goal of presymptomatic diagnosis, which could then facilitate earlier implementation of intervention.

Neural activation, as measured by fMRI, is starting to be utilized as a treatment outcome. Following 4 months of pivotal response treatment (PRT), a behavioral therapy designed to increase social motivation through naturalistic, play-based intervention, preschool and kindergarten-aged children with autism showed greater STS, FC, and PFC in response to biological motion, suggesting that treatment had increased (i.e., normalized)

activation in regions used by typically developing children during social perception. These findings are particularly interesting in that they demonstrate that the social brain areas may be malleable to treatment beyond the commonly accepted “critical period” for intervention (2–4 years). In addition, after 10 months of treatment with diuretic bumetanide, a drug that reinforces GABAergic inhibition, young adults with autism exhibited enhanced activation in the brain areas involved in social and emotional information processing from faces, highlighting the potential for drug intervention to change brain function. Though further study is needed, these preliminary findings suggest that fMRI may be a useful tool for quantifying treatment outcomes, with the goal of eventually identifying biomarkers of treatment response. Once these biomarkers are reliably established, treatment response may be able to be predicted based on neuroimaging findings, which would then help facilitate the customization of treatment plans to meet each individual’s specific needs.

While fMRI can be used to identify discrete areas of the brain that are active during certain cognitive processes, it can also be used to examine networks of brain regions involved in these processes, a method called functional connectivity analysis. For example, individuals with autism exhibited decreased synchronization between the inhibition network (anterior and middle cingulate gyrus and insula) and parts of the frontal and parietal regions relative to controls during an executive function task tapping response inhibition capabilities. Resting state functional connectivity has blossomed recently as a point of interest in the field. True to its name, resting state functional connectivity intends to locate neural networks in the absence of overt stimulation. This data is gathered during a “resting state” task, where the participant is asked to lie quietly and look at a blank screen. Resting state functional connectivity analyses have shown hypoconnectivity in many areas of the brain in children with autism, particularly in the temporal lobe and between hemispheres, as well as hyperconnectivity in subcortical areas such as the thalamus. Moreover, the mid- and posterior insula and posterior cingulate cortex have been identified as

areas of dysfunction in children with autism. Connectivity abnormalities seen in the default network, or the areas of the brain (such as the medial PFC, superior frontal gyrus, temporal lobe, and posterior cingulate cortex) that are active in the absence of overt stimulation, are associated with poorer social functioning and more severe restricted and repetitive behaviors. Functional connectivity analyses can inform understanding of how areas of the brain communicate with one another and how this communication may be disrupted in children with autism, which may further reveal biomarkers or potential targets for intervention.

Future Directions

Neuroimaging as a field, including the use and application of fMRI, is in its infancy relative to many other areas of study. The progress already made in advancing the knowledge of brain structure and function and the increasing complexity of the processes able to be studied highlights the incredible potential for impact in both research and clinical spheres. Scanning technology is improving constantly, from the gradient fields used to collect the images to the software that analyzes the data, underscoring the possibility of greater spatial resolution and a more precise delineation of neural activation. Methodological design in the field is also changing rapidly; it is now feasible to gather fMRI data and PET, ERP, MEG, or fNIRS data simultaneously. While this has been possible for nearly a decade, utilization costs have impeded widespread use until recently, particularly for combined fMRI-PET research, as these scans require a specially equipped MRI scanner. With the quality and capability of scanning technology increasing exponentially, it is likely that the use of these methods will flourish.

Recent advances in data acquisition and processing techniques have also allowed for the use of real-time fMRI neurofeedback as a method by which to encourage the acquisition of control over certain cortical processes, such as emotion regulation. Results from the relatively small number of studies that have utilized this method are positive,

highlighting the potential of this technique to inspire treatment progress. These advances may be particularly relevant to clinical practice, where the functionality of fMRI as a clinical tool has been slow to translate. The use of fMRI in diagnosing disorders before behavioral or physical symptoms develop, informing drug development and delivery, customizing treatment plans, and supporting treatment progress is bound to have a marked impact on the design and execution of clinical practice.

Furthermore, translational work that combines the study of neurobiology, genetics, and behavior is beginning to appear in world-class research facilities across the globe. For example, a current Autism Centers of Excellence (ACE) project focuses specifically on the etiology of autism in girls using a multisite collaboration design that spans the United States. This project examines the genetics of the disorder by gathering samples from typically developing children and children with autism, as well as the siblings and parents of both groups. In addition, fMRI and ERP are used to quantify neural activation to stimuli evoking the various cognitive processes thought to contribute to autism-related deficits. Finally, extensive behavioral measures, including cognitive, language, adaptive functioning, and autism symptom assessments, are collected from all children involved. Once completed, the study will be one of the most comprehensive ever done on the etiology of autism in general and specifically on what autism looks like in girls. The study will assist in elucidating the differences in the neurobiological, genetic, and behavioral profiles of girls and boys with autism, of children with autism and their unaffected siblings, and of those with autism and typically developing individuals. As recognition of the importance of research that crosses disciplinary and methodological boundaries grows, the number of studies employing translational principles is bound to increase markedly.

Functional magnetic resonance imaging is a powerful and widely applicable method for examining brain function. There is incredible potential for growth and progress within the field, and the possibility of widespread clinical use is in the foreseeable future. Specifically in autism, a better

understanding of the differences in brain function of children with autism is crucial to understanding key autism-related deficits, how to ameliorate them, and, perhaps most importantly, how to prevent the disorder's development altogether. Within the next few decades, more sophisticated technology and increased visibility of neuroimaging methods will hopefully inspire great strides in both research and clinical arenas.

Functional Routines (FR), Teaching

Katherine C. Holman
Department of Special Education, Towson
University, Towson, MD, USA

Definition

Information-processing deficits in individuals with autism spectrum disorders (ASD) inhibit

their ability to accurately attend to instructions, effectively participate in learning and social activities, and easily adapt to novel activities and change. Routines are effective at diminishing the information-processing load (Shatz 1983) by providing an inherent organizational structure that reduces variation and supports individual's participation in them (Constable 1986). The teaching of functional routines can assist individuals with ASD to be more successful in engaging in and completing everyday activities. Routines have the benefit of being sequential (McClannahan and Krantz 1999; Siegel-Causey and Guess 1989; Yoder and Davies 1992) and predictable (Prizant et al. 2006; Snyder-McLean et al. 1984) and are found in the natural environment (Pretti-Frontczak and Bricker 2004; Sussman 1999). Functional routines are predictable events that involve a chain of behaviors that are broken down into teachable units. They provide a reliable context that allows the individual to more independently participate or complete a specified activity. Functional routines instruction involves providing systematic prompts and cues to teach the child to participate independently in common school or home-based (self-care) routines (Arick et al. 2004). For example, the behaviors of arriving to school, hanging one's coat up in the locker, traveling to desk, and taking out materials for the day are all integrated behaviors that must be completed to achieve the function of this routine. The routines will vary upon the setting in which they are taught. If it is during the school day, they could consist of transitioning and arrival, participating in circle-time or classroom activities, using the restroom, greeting a peer, eating lunch, etc. If the functional routines are being taught in the home environment, they may consist of improving daily living skills, such as independently dressing, eating meals, playing a social game with a caregiver, or making leisure choices.

Historical Background

Routines have been described as a "scaffold" for children (Bruner 1975). Bruner and his

colleagues focused their research on the development of joint-action routines which promote shared attention, cooperative activity, and language development, for example, peekaboo, book sharing, or object exchange (Ninio and Bruner 1978). This use of routines was later adapted by McLean and Snyder-McLean (1987) as part of a communication intervention that focused on highlighting the identifiable cycles and turn-taking opportunities that were present in everyday routines, such as feeding or bathing. The use of routines has historically been implicated in various language interventions (see Constable 1986; Nelson 1986).

Functional skills are described as those that will have a meaningful impact on the individual's life. The importance of explicitly teaching skills that are functional and using a routine as the platform for teaching these skills has been a critical intervention focus, particularly with individuals with severe disabilities (Brown et al. 1976; Snell 1983; Wilcox and Bellamy 1982). Historically, a task-analysis model was used to identify the skills and activities that are functional for a student and then further divide the activity or routine into teachable units of behavior. Brown et al. (1987) offered the component model of functional life routines, which provides a systematic structure for the specification of behaviors relevant to student competence. The model was proposed to provide a more comprehensive approach to the identification of behavioral sequences that will lead to a more successful and independent completion of routines by the individual with a disability.

Specific research related to the use of functional routines with individuals with ASD is scarce; however, the concept has evolved from both language interventions (as described above) and the documented need to provide predictability and routine (Dawson and Osterling 1997) to promote participation and independence for individuals with ASD. Further, the use of routines is often a component in functional communication training, which is a common intervention used to improve the language and behavior of individuals with ASD (see Mancil 2006).

Current Knowledge

Limited research is available regarding the sole use of functional routines in teaching individuals with ASD. Often, the use of functional routines is naturally embedded as part of a comprehensive intervention program or classroom model (Arick et al. 2003; Dawson et al. 2010; Landa et al. 2011). The use of functional routines varies on the setting in which they are being used. In the school or workplace setting, they can be used as a generalization strategy after specific behaviors have been taught in a highly structured context (such as one-on-one using discrete trial training), and now they might be chained together in a more natural context (such as circle time) to promote participation or engagement in the routine.

The STAR program, Strategies for Teaching Based on Autism Research, identifies functional routines as one of the three primary instructional strategies (the other two being discrete trial training and pivotal response training) that comprise the intervention. The STAR program utilizes functional routines to assist the young child with ASD to independently participate in common school (e.g., participation in circle-time routines) and self-care routines (e.g., using the bathroom). The use of functional routines in this program assists with creating a structured learning environment. Arick et al. (2003) researched the use of functional routines in a preliminary outcome study of the program and noted it to be one of the most common one-to-one instructional strategies utilized in the population studied. A study by Stahmer et al. (2015) looked at the fidelity of implementation of the evidence-based practices within the STAR program for teachers within an urban public school classroom. The researchers found that with consistent and ongoing coaching and support, teachers were able to implement functional routines with a high level of procedural integrity. In a follow up study investigated the fidelity of implementation of the individual components of the STAR program as associated with gains in cognitive ability, even though teachers once again demonstrated high fidelity implementing functional routines, this strategy was not directly related to gains in cognition (Pellecchia et al. 2015). However, as discussed

below, the type of gains expected from the use of functional routines would be related to participation in activities and independence in self-care or school-based routines rather than a direct increase in cognitive abilities.

Rationale or Underlying Theory

The underlying theory for teaching functional routines is grounded in the need for creating a context that is predictable, repeated often (offering multiple opportunities to practice and participation), and comprised of smaller segments of functional activities that can be broken down and taught part by part. The behaviors taught as part of the routine are functional to ensure more independence in the individual's life. The routine can be conceptualized as a script (Bruner 1975) for the individual with ASD and reduce the cognitive load and improve their successful and independent participation in or completion of the activity (Nelson 1986).

Goals and Objectives

When identifying the goals and objectives associated with a functional routine, one must consider the functionality of the skills targeted within the curriculum or those required for completion of important activities in the life of an individual with ASD. Focus should be on those skills that (a) are most likely to be useful in the student's life to control his or her environment, (b) will increase the student's independence and quality of life, and (c) will increase the student's competent performance (Iovannone et al. 2003). The goal will most likely be to independently and successfully complete or participate in the specified functional routine. Each functional routine can be task analyzed into a number of core steps or behaviors, and these behaviors can be identified as the objectives. Independent mastery of each objective in succession will lead to the functional and independent completion of the routine. The ASD individual's specific strengths and needs, the context, and the actual steps or components of the routine will determine the specific goals and objectives.

Treatment Participants

Traditionally, the teaching of functional routines has been used with individuals with cognitive impairments and those with ASD. They can be utilized with very young children, related to creating routines for caregivers and children (Kashinath et al. 2006; Kern et al. 2007) or with older individuals who need assistance completing functional life skills (Iovannone et al. 2003; Ogletree et al. 2007).

Treatment Procedures

There is an inherent cycle for teaching functional routines, which includes (a) identification of a routine which is meaningful for the individual with ASD to complete independently, (b) task analysis of the steps and skills needed for a particular routine, (c) assessment of the individual's independent completion of each step or use of each skill to successfully participate or complete the routine, (d) direct instruction of each behavior/skill required in the functional routine, and (e) data collection on independence in participation or completion of the routine postinstruction. Further explanation of this cycle is below:

1. Identification of a functional routine. Determine what routine is meaningful for the individual with ASD to learn to complete independently. This could be to successfully arrive at work and prepare for the day, taking a bath at home, or participating in a song-gesture routine at circle time. The specific routine will depend on the context and the individual needs of the person with ASD.
2. Task analyze the steps and skills needed for a particular routine. The adult who will be teaching the functional routine should break down the routine into specific sequential steps and skills and identify what behaviors need to be taught for successful participation or completion of the routine.
3. Assessment of the individual's independent completion of each step of the routine. Prior to teaching the functional routine, the adult

instructor should complete a baseline measurement of the routine and measure the ASD individual's independence in completing each of the identified steps and skills in the functional routine. After collecting this information, the adult instructor should develop a lesson plan identifying the specific objectives (behaviors/skills) that need to be taught and the instructional procedures and strategies that will be used to teach the behaviors/skills for the routine.

4. Direct instruction of each behavior or skill in the functional routine. Depending on the needs of the individual with ASD, one might need to preteach each specific behavior individually using direct instruction. Once each step and behavior is mastered, then during the day, when the functional routine occurs, the instructor should provide the needed instruction and support for the individual to participate and complete each step of the routine.
5. Progress monitoring. Consistently monitor the ASD individual's successful and independent completion of the functional routine. If the individual has mastered the routine/related skills, restart the process, and identify a new functional routine. If not, return to instruction and reevaluate the instructional strategies.

The teaching of functional routines is typically carried out one-to-one or in a caregiver-coaching model. The particular routine that is taught will be determined by the functional needs of the individual within the particular context (e.g., home, school, or community).

Efficacy Information

There is limited efficacy data available for teaching functional routines.

Outcome Measurement

Outcome measurement for functional routines is related to the specific behaviors that are needed to successfully complete or participate in the routine.

These behaviors have typically been identified through the task analysis completed prior to teaching the functional routine. See further information described in the section “[Treatment Procedures](#).”

Qualifications of Treatment Providers

There are no specific qualifications for treatment providers. Treatment providers can be teachers, speech-language pathologists, caregivers, counselors, behavior therapists, job coaches, or other significant adults who work and who are familiar with the individual with ASD.

Functionally Equivalent Alternative Behavior

Kristen D'Eramo

The Center for Children with Special Needs,
Glastonbury, CT, USA

Synonyms

[Replacement behavior](#)

Definition

Functionally equivalent alternative behaviors, or functionally equivalent replacement behaviors, are desirable/acceptable behaviors that achieve the same outcome as a less desirable problem behavior. For example, an individual may shout

in order to gain his or her parent's attention when the parent is otherwise occupied. An alternative behavior that could serve the same function might be to say "Excuse me." In order to determine an appropriate alternative behavior, one must first understand the function of the problem behavior. This requires completion of a functional behavior assessment. Once the function of the problem behavior is clearly articulated, an appropriate alternative response, or repertoire of alternative responses, can be selected that are equal in function to the targeted challenging behavior. Alternative responses should be selected based on their social validity and should be more efficient than the challenging behavior. For example, saying "excuse me" and raising one's hand are both socially acceptable ways to gain attention and thus represent potential alternative behaviors. On the other hand, circling a person three times silently may be another way to gain attention without shouting but should not be selected because the behavior lacks social validity. Once an alternative behavior is selected, the individual should be specifically taught to engage in the behavior and then reinforced for doing so. In the current example, the child would be taught to say "excuse me" and then reinforced for doing so. In order to make the alternative behavior more efficient than the problem behavior, the problem behavior should not be reinforced or should be reinforced less often. In the example cited, the parent would consistently provide attention to the child when he or she says "excuse me" but ignore him or her when he or she shouts. In another example, a learner who engages in hitting others (problem behavior) in order to escape work demands (function) may be taught a functionally equivalent alternative behavior of requesting a break. The behavior of requesting a break allows the individual to meet his or her need (escaping the demand) without engaging in a socially inappropriate response. Approaches to intervention that seek to eliminate problem behaviors without teaching functionally equivalent alternative behaviors are ill advised as the individual will ultimately select his or her own ways to meet the needs that the extinguished problem behavior was previously serving. For example, a child who

shouts at his or her parent to gain attention could be taught to stop shouting for attention if the shouting is consistently ignored but over time he or she may begin hitting his or her parent in order to solicit attention if he or she is never taught what to do instead (e.g., say “excuse me”). Behavior support plans require explicit programming that addresses functionally equivalent alternative behaviors in order to best address individual needs. This includes specific teaching procedures for the alternative behaviors and plans to systematically reinforce the alternative behaviors when they occur.

Fusiform Gyrus (FG)

Danielle Perszyk
Yale Child Study Center, New Haven, CT, USA

Definition

The fusiform gyrus (FG) is a brain region consisting of occipitotemporal cortex (temporal lobe) that corresponds to Brodmann area 37. It is involved in high-level visual processing, specifically object recognition and category identification, of complex stimuli such as faces. Individuals

with ASD demonstrate deficits in certain cognitive abilities for which the fusiform gyrus has been implicated – most notably and socially relevant being face processing – as well as abnormalities in the fusiform gyrus itself.

Historical Background

The fusiform gyrus is a brain region involved in high-level visual processing. Visual processing is organized hierarchically and involves many brain regions working together to transform information provided by the external world into internal representations. Early low-level visual processing occurs milliseconds after light hits the retina and distinguishes basic, isolated features such as orientation, spatial frequency, and color. Later high-level visual processing combines information from lower levels of processing and culminates in identification, recognition, and categorization of objects and actions. Visual processing begins in occipital cortex and proceeds anteriorly via ventral and dorsal pathways; the highest levels of processing occur in temporal cortex. The ventral and dorsal pathways are hypothesized to represent the processing of “what” and “where/how” information, respectively, and are correspondingly associated with “perception” and “action” (Underleider and Mishkin 1982). The FG has been shown to be involved in numerous ventral stream processes, including high-level visual processes that entail semantic encoding.

The initial discoveries concerning specific functions of the FG arose from studies of primates (Van Essen et al. 1992) and patients with brain lesions or psychological disorders (Mesulam 1994), both of which have revealed the anatomy of the mammalian visual system. First, single-unit recordings from the inferotemporal cortex in macaques found populations of neurons that responded specifically to faces (Gross et al. 1972). Then, electrophysiological studies in humans suggested similar cortical specialization. Recordings from the same brain region in epilepsy patients with implanted subdural electrodes showed large N200 potentials elicited by faces but not scrambled faces, cars, or butterflies

(Allison et al. 1994). These studies were consistent with an older study of brain-injured patients that showed the same brain region seemed to be involved in recognizing faces but not houses (Yin 1970). Additional studies of patients with damage to occipitotemporal cortex of the right hemisphere, who had selectively lost the ability to recognize faces, further supported the notion that this region is involved in face processing (DeRenzi and Saetti 1997). At the same time, research in several areas, including cognitive psychology, neuropsychology, neurophysiology, and computational vision, converged to suggest the differentiation of face and object recognition as qualitatively different processes and perhaps even entailing distinct brain areas.

As research continued building an understanding of the function of the FG, a growing body of evidence indicated that face processing was not its only function. Neuroimaging became more popular as a technique to study brain function, and as a result, specific brain regions could be much more easily implicated in a wide range of cognitive processes, including processing shape and surface properties such as color and texture (Barrett et al. 2001), number and word recognition (Allison et al. 1994), and within-category identification (Gauthier et al. 2000). Yet while these studies showed that the FG is involved in myriad visual process, individuals with ASD do not characteristically demonstrate deficits in the lower level visual processes (e.g., shape and surface properties); rather, they often demonstrate difficulty integrating more basic features into configural representations and processing certain higher level visual categories, specifically the socially relevant category of faces. Early research investigating face processing in ASD showed that, unlike typically developing peers, children with ASD fail to show both a “face inversion effect” – a disproportionate difficulty recognizing upside down faces – and a face “decomposition effect” – reduced recognition of face components or partially obscured faces (Langdell 1978). That is, children with ASD do not show more difficulty recognizing upside down faces than upright faces, nor do they show more difficulty recognizing face components or partially obscured faces than

whole faces. These abnormalities in face processing suggest that, unlike typical counterparts, individuals with ASD do not process faces holistically (Freire et al. 2000), but instead, they may process faces using feature-based strategies similar to how typical people process objects.

Given that ASD is at its core a social disorder and that face perception is among the most vital of social functions, it is especially noteworthy that individuals with ASD were observed to process faces atypically. But it remained uncertain whether these face-processing abnormalities stem from a primary brain abnormality, a primary behavioral difference (i.e., lowered attention to faces), or some combination and subsequent interaction thereof. Studies found that individuals with ASD already show lower attention to faces as young as 1 year of age (Osterling and Dawson 1994); by childhood, they show more difficulty than typically developing children discriminating and recognizing (Boucher and Lewis 1992) faces, and through adolescence and adulthood, they continue to show poorer recognition of faces than typically developing counterparts (McPartland et al. 2004). In order to disentangle the possible origins of these behavioral deficits in face processing – whether they arise from primary brain abnormalities or primary behavioral differences – later studies used neuroimaging techniques to examine the brain bases of face processing in ASD. Functional magnetic resonance imaging (fMRI) studies showed that, when viewing neutral faces, individuals with ASD exhibit lowered fusiform gyrus activity compared to typical counterparts (Schultz et al. 2000). Furthermore, Schultz et al. (2000) suggested that individuals with ASD process faces more similarly to how typical counterparts process objects, with decreased FG activity and increased inferior temporal gyrus activity. Event-related potential (ERP) studies showed that children with ASD, but not typically developing children, fail to exhibit differential brain activity for familiar versus unfamiliar faces (Dawson et al. 2002); similarly, adolescents and adults with ASD, but not typical counterparts, fail to exhibit differential brain activity for upright versus inverted faces (McPartland et al. 2004). Moreover, McPartland et al. (2004) found that

individuals with ASD exhibit longer latencies to faces and that processing speed positively correlates with face recognition ability. These face-sensitive ERPs have been localized to the FG. Finally, one recent study found that individuals with ASD have smaller and fewer neurons in the FG (van Kooten et al. 2008).

Current Knowledge

Initial investigations of the FG revealed its involvement in face processing. While it has since been implicated in many additional roles, current investigations continue to focus on the role of the FG in face processing. There are presently three prevailing theories for the neural organization of face processing involving the FG. One is that the FG is specialized for face processing, which is modular and domain specific (Kanwisher et al. 1997). A second theory is that the FG is not specialized for faces per se but for objects with which one has experience or expertise; most humans have extensive experience with and are thus “experts” of faces, making the FG specialized for faces by default. This theory proposes that the FG is domain general, and it may also serve to differentiate between specific levels of categorization, particularly subordinate levels of identification (Gauthier et al. 2000). A third theory is that the FG and, more generally, inferotemporal cortex are neither specialized for face nor object processing but for face-like features. That is, the brain region containing and surrounding the FG is topographically arranged according to visual features of objects, and the FG “happens to be” where types of visual features associated with faces are processed (Haxby 1999).

It still remains uncertain as to which, if any, of these theories most accurately describes the role of the FG as it relates to face processing. Moreover, these theories do not comprehensively reflect face-processing research. Yet other studies suggest that face processing and the role of the FG are affected by the manner in which one conceives a visual percept. Specifically, thinking about a visual percept in a social context or imagining faces may be sufficient for FG activation. Schultz

et al. (2003) found that the FG activated for geometric shape stimuli behaving in social but not mechanistic ways, suggesting that FG activity is dependent upon a social framework. While this interpretation is inconsistent with any of the above three theories, it is consistent with findings from other studies. These unreconciled findings have important implications for the source of social dysfunction in ASD. A major question is whether the observed abnormalities in face processing in ASD are causes or effects of the diagnostic social deficits in ASD. While some studies argue the former (Trepagnier 1995), most evidence supports the latter; children with ASD may have experienced typical development with appropriate attention to faces early on followed by autistic regression, and individuals with ASD exhibit abnormalities in widely distributed brain systems, some of which are unrelated to face processing (Kemper and Bauman 1998). A larger body of research suggests that face-processing difficulties stem from developmental abnormalities in social interest and attention. Individuals with ASD may exhibit face-processing deficits because they do not acquire adequate experience with faces due to a lack of social motivation (Dawson et al. 2002). This theory is consistent with both the domain-specific and domain-general theories of face processing aforementioned. Another explanation of face-processing abnormalities in ASD that has not been empirically supported is that they stem from early developmental abnormalities in the FG or, more generally, inferotemporal cortex.

Schultz and colleagues (2005) have proposed that face perception and social cognitive skills are part of a network supported by a system comprised of the amygdala and FG and that abnormalities in this brain system, which in turn cause deficits in the social perceptual network, may play a large role in the etiology of autism. They argue that the best neuroimaging evidence for brain-based differences in the ASDs thus far involves FG hypoactivation, and they describe three possible interdependent factors that might moderate the degree of FG activity in ASD. First, they suggest an attentional factor: lowered attention to a visual stimulus reduces FG activity. Second, they suggest a perceptual skill factor:

chronically reduced attention to social stimuli, particularly faces, leads to reduced perceptual skill and reduced FG activity. Third, they suggest a social knowledge factor: the FG may encode social knowledge such that social judgment not necessarily involving faces may strongly activate the FG, and therefore, conversely, reduced social knowledge may reduce social judgments, which in turn may result in FG hypoactivation.

Two recent studies have provided a confound to this model. Dalton et al. (2005) found that when individuals with ASD view faces, amygdala and FG activation are strongly and positively correlated with time spent fixating the eyes. In addition, eye fixation is strongly and positively associated with amygdala activation, suggesting a heightened emotion response associated with eye fixation. Similarly, Morris, Pelphrey, and McCarthy (2007) found that when typically developing individuals view faces, the scanpath one follows alters FG activation such that greater focus on the eyes (typical scanpath) as opposed to other face regions (atypical scanpath) elicits greater FG activation. These findings indicate that, in addition to degree of attention, the specific features attended to within social stimuli (i.e., faces) affect FG activation. These findings therefore imply that controlling gaze fixation for individuals with ASD when viewing social stimuli may serve to alter the neural mechanisms underlying their social deficits.

Future Directions

Further research concerning FG function will continue to disentangle the various models of face processing and, concerning the etiology of ASD, whether FG abnormalities are primary or whether deficits in social motivation and ability are primary to deficits in social skills. In addition, future neuroimaging studies will seek to investigate the effects on FG activation of various scanpaths for social stimuli in individuals with ASD. These studies will contribute to a refining of the understanding of both the causes of and potential treatments for ASD.

Definition

Gabapentin is an anticonvulsant medication that is also used for the treatment of anxiety. It is also used for the treatment of bipolar illness. The mechanism of action of gabapentin is complicated and not completely understood. It appears to assist with the decreased excitability in the brain. However, it does not appear to directly affect the GABA system in the brain. Recent evidence suggests that it exerts its positive effects by turning down calcium channels. This would fit with its effect to decrease excitability in the brain.

There are no studies of gabapentin in children with autism spectrum disorders. However, it is used as an anticonvulsant in children.

Canada

Children with autism spectrum disorder (ASD) have difficulties in social interactions, affecting their social participation and quality of life. There is a growing use of assistive technologies to support social participation of children with ASD. Despite potential improvements of social skills after using these programs, there are concerns on technology dependence and generalization of learned skills. It is still unclear to what extent virtual environments are effective and what populations on the autism spectrum are the suitable candidates to take advantage of using virtual gaming programs. This manuscript highlights trends in current literature and recommends ideas for future studies.

Definition and Historical Background

Autism spectrum disorder (ASD) is a childhood neurodevelopmental condition that is currently being diagnosed in about 1 in 59 children. Children with ASD may experience difficulties in communication and socio-emotional skills, which affect their daily functioning (American Psychiatric Association 2013; Baron-Cohen et al. 2001; Simonoff et al. 2008). Children with ASD have challenges with understanding and applying social rules and interpreting verbal and nonverbal social cues (Kelly et al. 2008; Ghanouni et al. 2019). All these factors can have repercussions for the child's ability to socialize, develop relationships, and make friends. As children get older and gain insights about these significant deficits, they demonstrate decreased self-

esteem in communicating with their peers (Lopata et al. 2008). This may act as a vicious cycle that precludes children from acquiring social skills to interact appropriately with peers.

The delivery of early and effective therapeutic services is crucial to enhance the outcomes and functioning of clients with ASD (Eikeseth 2009; Matson and Smith 2008). Gaming programs have been widely used in the fields of education and rehabilitation to address a diverse range of clients' needs. These programs provide an opportunity for practicing in a fun environment with gradual exposure to stimuli, providing consistency and stimulus control, giving real-time feedback, and augmenting attention to performance (Parsons and Cobb 2011). These programs can provide a simulated environment in which the intensity of training, level of difficulty, and amount of feedback can be adjusted. Virtual gaming programs can simulate real-life situations, which increases the probability of transferring learned skills to real-life contexts, and provide a safe and risk-free environment to practice skills that may be dangerous or risky to complete in real-life contexts (Bellani et al. 2011). This allows for the creation of an individualized program that keeps clients motivated to endure the program.

Current Knowledge

Recently, there have been rapid advancements in developing low-cost technologies in rehabilitation, including computer-based programs, virtual reality games, motion-tracking games, and video games (Anderson-Hanley et al. 2011; Parsons and Cobb 2011). However, developing an appropriate program for children with ASD is a complex task due to the heterogeneity of the disorder and co-occurring conditions (Wilczynski et al. 2007). Not every program can fit the broad range of needs that may be observed in individuals on the spectrum. It is necessary to tailor each program to address the symptoms and deficits that a child with ASD demonstrates. In addition to the importance of individualized programs, the involvement of clients in making decisions about the program to suit their family style and preferences

would maximize outcomes (Elwyn et al. 2000; Guadagnoli and Ward 1998).

Looking at the literature, there has been mixed findings on potential effects of using video game and virtual reality programs in individuals with ASD (Parsons and Cobb 2011). Some of the literature did not show significant results, whereas others demonstrated significant improvements in socio-emotional skills. Gaming programs were demonstrated to be effective for improving specific social skills, such as social initiation/interaction, verbal communication, and facial affect and emotion recognition for children diagnosed with ASD. Using humanoid or cartoon characters in computer-based intervention programs has been shown to potentially improve emotion recognition in individuals with ASD (Golan et al. 2010; Hopkins et al. 2011; Tanaka et al. 2010). Increased perspective-taking and a higher level of social interaction within short-term usage of the computer-based interventions, as complementary programs, hold great promise for individuals with ASD (Hughes 2014; Golan et al. 2010; Moore et al. 2000; Mesa-Gresa et al. 2018). The majority of the findings demonstrated positive trends for social skill development but lack the rigor and power to reach levels of significance.

Although there was no reported negative experience of using these gaming programs, there are concerns on the dosage of the program and the extent to which users of video games can generalize the learned skills to real life. If the task can only be performed in a virtual setting and in a controlled environment, the benefits of the program should be justified. Using the virtual settings, which include real-life scenarios, helps individuals with ASD relate to these scenarios when they face them in real life. Adjusting the level of difficulty of the task, as individuals with ASD progress over time, keeps them engaged in the activities. Modification of sensory, visual, and auditory modalities should also be considered when working with individuals with sensory problems. Given the interest of individuals with ASD to use virtual settings, screen time and technology dependence are other concerns (Montes 2015). The optimal goal is helping users to be independent, and not mentally reliant on technology that may affect the quality of daily

interactions. Although setting schedules might help monitor screen time, there is still a significant gap in the literature on how we can mitigate potential risks of using virtual settings and appropriate dosage of programs to facilitate learning new skills in individuals with ASD.

In addition to the content of virtual settings, another presumption is that not everyone can be an ideal candidate to use it. Being able to navigate through virtual environments, relate scenarios, and transfer learned skills to daily life requires high levels of practice, environmental support, as well as individual mental and functional capacity. Severity of disorder, selective and sustained attention, executive function, and IQ level might be factors that play significant roles for transition of learned skills from virtual settings to daily activities.

Future Direction

Identifying subgroups of individuals with ASD who have the potential to benefit from using these virtual settings is a recommendation for future research. Providing more comprehensive profiles, using brain imaging to examine areas that are activated in virtual settings as opposed to real settings, and seeking potential differences in brain functions provide additional insight in deciding which tool, when, and how they might be useful (Bohil et al. 2011; Weber et al. 2006). Given the heterogeneous nature of ASD and disperse behavioral studies, brain imaging techniques such as EEG can advance knowledge and provide additional understanding of the extent in which a simulated virtual environment is similar to in vivo settings. Following up with participants of the study after receiving gaming programs to examine the degree in which the learned skilled can be generalized to other settings and/or maintained after a period of time is also warranted. Additionally, future research will need to consider more rigorous studies using stronger study designs by increasing sample size, addressing co-intervention, comparing different types of gaming programs, and using outcome measures with strong psychometric properties. As a result, informed modifications can be made

to potentially optimize learning in virtual settings for individuals with ASD.

Definition

Gangliosidosis contains different types of lipid storage disorders caused by the accumulation of lipids called gangliosides. Gangliosides are made and biodegraded rapidly in early life as the brain develops. The two main types of gangliosidosis are GM1 gangliosidosis and GM2 gangliosidosis, and these have two distinct genetic causes. Both

types are autosomal recessive, meaning that both copies of the gene in each cell have the mutation, and affect males and females equally. This disorder occurs in 1 in 100,000–200,000 newborns.

GM1 gangliosidosis is an inherited disorder caused by mutations in the GLB1 gene, which is a gene that provides instructions for making an enzyme called beta-galactosidase and is located in the lysosomes. Beta-galactosidase helps break down several molecules including the GM1 ganglioside and is important for normal functioning of nerve cells in the brain. Buildup of GM1 gangliosides leads to destruction of nerve cells in the brain and spinal cord. GM1 gangliosides are inherited, autosomal recessive sphingolipidoses, resulting from marked deficiency of acid beta-galactosidase. Diagnosis can be made by either enzyme analysis of the beta-galactosidase enzyme or by molecular genetic testing of the GLB1 gene. Enzyme activity may determine diagnosis, but it is not necessarily predictive of carrier status in the relatives of affected people. Prenatal diagnosis of GM1 gangliosidosis is possible by measurement of acid beta-galactosidase in cultured amniotic cells. There is no effective medical treatment, other than symptomatic and supportive treatments. Symptomatic treatment for neurological signs and symptoms, such as anticonvulsants for seizures, does not alter progression of the condition. Supportive treatments include proper nutrition and hydration. Additionally, there is potential benefit from physical and occupational therapy. There is active research in areas of enzyme replacement and gene therapy, but this has not yet been advanced to human trials.

The three types of GM1 from most to least severe are Early Infantile GM1, Late Infantile GM1, and Adult GM1. The onset of Early infantile GM1 occurs shortly after birth and usually becomes apparent by the age of 6 months. Symptoms include neurodegeneration, seizures, liver and spleen enlargement, coarsening of facial features, skeletal irregularities, joint stiffness, distended abdomen, muscle weakness, exaggerated startle response to sound, and problems with gait. Diagnosed children may be deaf and blind by age 1. Half of patients with

GM1 develop cherry-red spots in the eye. These children often die by age 3 from either cardiac complications or pneumonia. The onset of Late Infantile GM1 is usually between 1 and 3 years old. Neurological symptoms include ataxia, seizures, dementia, and difficulties with speech. These children also experience developmental regression, but no cherry-red spots, distinctive facial features, or enlarged organs as seen in Early Infantile GM1. The progression is slower than Early Infantile GM1 but still causes a shortened life expectancy. The onset of Adult GM1 is between 3 and 30 years old. Typical symptoms are muscle atrophy, neurological complications, corneal clouding, and dystonia. This is the mildest form of GM1 and life expectancy is quite variable.

GM2 gangliosidosis results from mutations in at least 1 of 3 recessive genes (HEXA, HEXB, GM2A). The products of these three genes are the alpha subunits of b-hexosaminidase A, the beta subunits of Hex A, and the GM2 activator protein. GM2 encompasses a group of three related genetic disorders that results from a deficiency of beta-hexosaminidase, an enzyme found in the lysosomes that catalyzes the biodegradation of gangliosides. In GM2, a harmful quantity of gangliosides accumulates in the brain's nerve cells, leading to premature death of cells. The signs and symptoms become apparent in infancy. Infants appear normal until 3–6 months of age when development slows and muscles used for movement weaken. Infants often develop exaggerated startle reaction to loud noises, as well as seizures, vision and hearing loss, intellectual disability, paralysis, and cherry-red spots in the eye as the disease progresses. All three GM2 disorders are extremely rare in the general population. All are associated with failure of the same metabolic pathway and have the same outcome, but each represents a distinct molecular point of failure in a subunit that is required for activation of the enzyme.

Tay-Sachs disease is the most common of the GM2 gangliosidoses. It is an autosomal recessive genetic disorder caused by a mutation in the HEXA gene and results in GM2 ganglioside storage in the central nervous system (CNS).

Tay-Sachs usually develops around 6 months of age and results in death by age 4. Sandhoff disease is an autosomal recessive metabolic disorder caused by mutations on chromosome 5 in the HEXB gene. The most common form is infantile Sandhoff disease, which is fatal in early childhood. Sandhoff disease is clinically indistinguishable from Tay-Sachs disease. The third type of GM2, AB Variant, is an autosomal recessive metabolic disorder caused by a mutation in the GM2A gene. The GM2A gene provides instructions for making a protein called the GM2 activator, which is a cofactor that is required for the normal function of beta-hexosaminidase A. All three types of GM2 are extremely rare and normally fatal by early childhood. There does not appear to be a correlation between clinical disease progression and survival in GM2 gangliosidosis. The main reasoning for this lack of correlation is most likely due to the impact of improved supportive care over time.

As gangliosidosis is a rare disorder, there is a deficiency of research on the relation between gangliosidosis and autism spectrum disorder (ASD). GM1 gangliosides in the cerebrospinal fluid (CSF) were found to be increased in individuals with autism compared to age-matched controls and those with non-progressive neurologic disorders. This increase of CSF gangliosides in the synaptic junctions indicates enhanced activity of the inhibitory synapses. Proper glycoprotein sialylation is necessary for synaptic function and a sialylation deficiency in the CNS is related to the occurrence of ASD.

Definition

Autism spectrum disorders (ASDs) are a group of developmental disorders characterized by impairments in social interaction; varying degrees of verbal and nonverbal communication deficits; and restricted, repetitive, and stereotyped patterns of behavior and interests. The term includes autistic disorder, Asperger disorder, and pervasive developmental disorder, not otherwise specified (PDD-NOS) (Johnson et al. 2007).

A meta-analysis representing the first rigorous evaluation of evidence regarding GI symptoms in children with ASD, quantifying the past 32 years of research, indicate greater risk of general GI symptoms among children with ASD than in those without ASD, indicating that this population may be more prone to specific symptoms of abdominal pain, constipation, and diarrhea by greater than two- to threefolds (McElhanon, 2014).

In these children, a variety of gastrointestinal dysfunctions and associated symptoms have been reported frequently. Gastrointestinal problems in individuals with ASDs can be challenging to evaluate. Clinical practice guidelines exist for the evaluation and management of ASDs by primary care and other physicians responsible for the care of individuals with ASDs but do not include routine consideration of potential gastrointestinal and other medical problems (Volkmar et al. 1999).

Many individuals with ASDs are nonverbal or minimally verbal and cannot express pain or discomfort through speech. As a result, they may not be able to communicate information about their symptoms. Even individuals with ASDs who acquire verbal communication skills may have difficulty describing subjective experiences or symptoms. In addition, the magnitude of the observed association combined with difficulties identifying and studying GI dysfunction in ASD warrants the adoption of a lower referral threshold by practitioners for evaluation and treatment by a gastroenterologist if an underlying problem is suspected.

Historical Background

Autism spectrum disorders (ASDs) are clinically heterogeneous neurodevelopmental disorders.

Gastrointestinal (GI) dysfunction is frequently cited among children with ASD, and many causal and therapeutic hypotheses of ASD involve the GI system. This includes the idea that there is a specific GI pathology associated with ASD, triggered by abnormal immune function or elevated intestinal permeability.

A great amount of controversy has surrounded this topic since publication and public awareness

in 1998 naming a new pathologic entity, “autistic enterocolitis,” (Wakefield et al. 1998) as responsible for developmental regression in 12 children after administration of the measles-mumps-rubella (MMR) vaccine. Ultimately, this research was retracted. Additional theories have posited that children with ASD are at greater risk for gluten sensitivity (Lau et al. 2013), lactase deficiencies (Williams et al. 2011), and gene variants (genetic evidence implicating genes in the METreceptor tyrosine kinase pathway in ASD) (Campbell et al. 2008). Although the presence of a unique GI pathophysiology specific to ASD’s has yet to be identified, elevated risk for GI symptoms in this population remains a critical issue in pediatric settings, because this population is significantly more likely to use GI agents and experience hospitalizations related to GI disturbance compared with peers (Croen et al. 2006).

In addition, key issues such as the prevalence and best treatment of these conditions are incompletely understood. A fundamental difficulty in recognizing and characterizing gastrointestinal dysfunction with ASDs is the communication difficulties experienced by many affected individuals. A multidisciplinary panel reviewed the medical literature with the aim of generating evidence-based recommendations for diagnostic evaluation and management of gastrointestinal problems in this patient population. The panel concluded that evidence-based recommendations are not yet available (Buie et al. 2010a). The consensus expert opinion of the panel was that individuals with ASDs deserve the same thoroughness and standard of care in the diagnostic workup and treatment of gastrointestinal concerns as should occur for patients without ASDs. Problem behaviors may be the symptoms of underlying gastrointestinal disorders. Insufficient data were available to determine whether GI symptoms often linked with an organic pathology. Questions also remain about the relative contribution of behavioral factors, such as toileting and feeding problems, to the observed association between diarrhea, constipation, and abdominal pain in ASD. An approach that identifies and treats medical problems simultaneously with behavioral symptoms may be necessary. Further research is

necessary to better characterize the nature of the gastrointestinal symptoms experienced by individuals with autism as well as the biological etiology.

Current Knowledge

Chronic Abdominal Pain

Chronic abdominal pain is defined as intermittent or constant abdominal pain that exceeds 1 or 2 months in duration. For children with ASDs, assessment may be challenging. Although underlying causes of chronic abdominal pain are frequently benign, parents are often worried that the child with an ASD is in gastrointestinal distress and that the clinician should be concerned about missing a serious disease. Generally, for children without ASDs between the ages of 4 and 18 years, functional abdominal pain can be diagnosed correctly by the primary care practitioner when alarm symptoms (e.g., involuntary weight loss, deceleration of linear growth, gastrointestinal blood loss, significant vomiting, chronic severe diarrhea, persistent right upper or right lower quadrant pain, unexplained fever, family history of inflammatory bowel disease, abnormal or unexplained physical findings) are absent, results of the physical examination are normal, and stool does not contain occult blood. There are no specific and reliable signs or symptoms that enable the health care provider to distinguish between organic and functional disorders. Children with ASD may be able to communicate distress with language, but many have atypical communication and may express abdominal pain with unusual behaviors (e.g., pressing on the abdomen and tapping on the areas of distress) or change in state of being (e.g., sleep disturbance, self-injurious behavior, and aggression) that may not be perceived as indicating the source of the discomfort (Horvath and Perman 2002). The presence of any alarm symptom should initiate an evaluation. Even in the absence of alarm symptoms, a diagnostic evaluation or empiric trial of a therapeutic intervention may be considered. Education is an important part of treatment. In the absence of alarm symptoms and after an unrevealing diagnostic evaluation and failure of empiric treatment to resolve the

symptom or behavior, it may be helpful to review with the family the child's symptoms and explain that although the pain is real, there is no evidence at present of a serious or chronic disease. The clinical picture can change over time, and individuals with ASDs should be reevaluated if their symptoms or signs change.

Constipation

Constipation is the occurrence for 2 weeks or so of a delay or difficulty in defecation. The causes of constipation are many and may be organic or nonorganic; medications can be a potential cause (e.g., opiates, phenobarbital, antacids, sucralfate, anticholinergics, antidepressants, sympathomimetics, antihypertensives) (Constipation Guidelines Committee of the North American Society for Pediatric Gastroenterology, Hepatology and Nutrition 2006). Children with ASDs can have sensory processing abnormalities and develop stool-withholding behaviors or constipation related to altered pain responses. Even children with ASDs who have daily bowel movements may have retention of stool that is not evident to parents, teachers, or health care providers.

The evaluation of all children who present with constipation should include a thorough medical history and physical examination. Information from the history and physical examination usually enables the physician to determine if further evaluation is warranted or if functional constipation is present. Determination of what the family or child means when they use the term "constipation" is important. The history should delineate the frequency of bowel movements, the consistency and size of stools, and whether the child experiences abdominal pain. A history of stool-withholding behavior reduces the likelihood of a causative organic condition. For children with ASDs, the physical examination may not identify palpable stool in the left lower quadrant, and a careful rectal examination might not be feasible. Every attempt should be made to examine the rectum, although at times this cannot be accomplished. The rectal examination enables assessment of stool retention, anal tone, and occult mass, as well as the presence or absence of blood and helps to reassure the family that the child's anatomy is normal. It

need not be repeated on subsequent visits unless there is a change in the history or physical examination. A plain radiograph of the abdomen may reveal a rectal fecal mass not palpable on the abdominal examination. If large amounts of stool are found on rectal examination, an abdominal radiograph is not needed to establish the presence of fecal impaction (Constipation Guidelines Committee of the North American Society for Pediatric Gastroenterology, Hepatology and Nutrition 2006). Diagnostic clues can help to identify some organic causes of constipation. Hirschsprung disease is not less common in children with ASDs, and a history of delayed passage of stool after birth should raise suspicion of aganglioneurosis. Anatomic abnormalities such as an anteriorly displaced anus, which is more common in girls than boys, can be diagnosed by careful inspection of the rectum. Children with altered intestinal motility may have underlying mitochondrial disease (Chitkara et al. 2003). Recent studies have suggested a potential association of ASDs and mitochondrial dysfunction (Oliveira et al. 2005).

Treatment of constipation includes mineral oil, magnesium hydroxide, lactulose, sorbitol, and polyethylene glycol (PEG), or a combination of lubricant (mineral oil) and laxative is recommended for the daily management of constipation in children.

Chronic Diarrhea

Chronic diarrhea occurs when loose stools persist for 2 weeks or longer, with or without an increase in stool frequency. Most episodes of acute diarrhea resolve within a week and are frequently caused by self-limited infections. In contrast, the causes of chronic diarrhea more frequently include noninfectious causes than for acute diarrhea. In the US general pediatric population, the most common causes of chronic diarrhea are functional disorders, malabsorption syndromes, inflammatory bowel disease (Crohn disease or ulcerative colitis), and chronic infections. The causes of diarrhea in children with ASD are likely the same as in children without ASDs, and the differential diagnosis should be approached with similar rigor. Chronic nonspecific diarrhea of

childhood can first present between 6 and 36 months of age and often resolves by 60 months of age. It is characterized by loose and sometimes frequent stools and, importantly, the absence of other abnormalities such as growth failure, abdominal pain, and difficulty in passing stool. If the latter signs or symptoms are present, other causes of chronic diarrhea should be considered. Guidelines for the diagnostic evaluation of chronic diarrhea have not yet been developed, but recommended approaches are available in standard pediatric gastroenterology texts (Guarino and De Marco 2008). These same approaches are relevant for the child with an ASD. A careful history and physical examination are important and include definition of the age at symptom onset and whether symptoms develop abruptly or gradually. Causes of chronic diarrhea in children include enteric infections, immunodeficiency, abnormal immune response, inflammatory bowel disease, congenital persistent diarrhea, hereditary lactase deficiency, chronic nonspecific diarrhea of childhood, and syndromic persistent diarrhea and malnutrition (in developing countries and worldwide). Family history of allergy or atopic disease may increase the likelihood of cow's milk allergy. It is important to assess a child's growth and nutrition. Poor weight gain may be a result of malabsorption or inadequate or inappropriate feeding; delayed growth may then be the result of a child being fed a diluted, hypocaloric formula or clear liquids in an effort to reduce diarrhea. In contrast, for infants or children who appear to be thriving or overweight while suffering from chronic diarrhea, a careful dietary record for 1 week may determine if a patient is being overfed or drinking excessive amounts of fruit juices that are known to induce diarrhea. A functional cause of chronic diarrhea is suggested by protracted symptoms (12 months) or lack of significant weight loss, nocturnal diarrhea, and straining with defecation. Loose stool in children with ASDs may be misdiagnosed as diarrhea. Constipation is a common, albeit somewhat paradoxical, cause of loose stool and may be difficult to confirm by history or physical examination. Stool might not be palpable in the left lower quadrant, and a rectal examination may be challenging and traumatic for the child. A plain abdominal radiograph may be useful. Frequently, an empiric trial with a

stool softener, such as PEG 3350 (MiraLAX) for 2–4 weeks, supports the diagnosis by causing a change in behavior. Lactose intolerance can be difficult to diagnose. A diagnostic trial of a strict lactose-free diet may be difficult to maintain, especially for a patient for whom food choices are limited. A lactose breath test (LBT), which requires an overnight fast and repeated collection of breath samples over 3 h, can be difficult to perform on some children. Similar information can be obtained at the time of an upper endoscopy via tissue analysis for disaccharidase-specific activity.

Food allergy, another but less frequent cause of diarrhea, is often challenging to diagnose because most instances of intestinal food allergy are cell mediated rather than mediated by immunoglobulin E (IgE). IgE-based tests may not identify individuals who do not have atopic or immediate reactions, and IgG-based tests are of no value in assessing intestinal food allergy. Referral to an allergist for skin testing may be appropriate. Assessment for celiac disease should be performed for any child with an ASD and gastrointestinal symptoms. Testing at a minimum should include a total IgA level, tissue transglutaminase IgA antibodies with or without endomysial IgA antibodies. Antigliadin antibodies are less reliable. Stool samples to test for enteric pathogens, ova/parasites, or occult blood can be obtained easily at the time of a lower endoscopy but otherwise may be difficult to collect. Biopsies of the colon and ileum are routinely obtained on endoscopy and determine whether there is acute or chronic mucosal inflammation. Therapeutic interventions vary depending on the cause of chronic diarrhea.

Gastroesophageal Reflux Disease

GER, the term for passage of gastric contents into the esophagus, can produce diverse symptoms and complications, called gastroesophageal reflux disease (GERD). During infancy, in contrast to nonpathologic reflux, GERD presents most frequently as an adverse effect of recurrent vomiting but also as apparent life-threatening events (ALTE). As a child matures, other symptoms and signs of GERD include chest pain or heartburn, esophagitis, food refusal, and extra-esophageal manifestations of the airway. As in

children without ASDs, the expression of disease related to GER can vary widely in children with ASDs. Certain children may express discomfort through problem behaviors, restriction of foods of specific texture, or simply pointing to their chest. Objective measures become important to elicit from the patient and family, such as the frequency and timing of regurgitation, the character and amount of material regurgitated, and the kinds of foods that are tolerated by the child. The presenting symptom or sign is a clue to the underlying cause. Children with ASDs who have obstruction caused by, for example, malrotation or antral web may regurgitate many times an hour, whereas those individuals who have typical GERD may experience symptoms when they lie down at night or after meals. The vomiting of undigested foods suggests a delay in gastric emptying; hematemesis suggests the presence of inflammation or ulceration. In young children, a preference for liquids or a refusal to eat textured foods or foods that require chewing should raise suspicion of esophagitis.

Diagnostic evaluation begins with a careful history and physical examination. In some children more than 2 years of age, recurrent regurgitation or vomiting disrupts their participation in childhood activities. As for children without ASDs, an empiric trial of acid suppression may be of diagnostic value, but then the clinician may want to order an upper gastrointestinal series to exclude an anatomic abnormality, as well as upper endoscopy with biopsy to look for inflammation associated with GERD, allergy, or eosinophilic esophagitis. Other warning signals for additional diagnostic testing include gastrointestinal bleeding, abdominal tenderness, and fever. A diagnostic trial of acid suppression, with an appropriate dose of a proton pump inhibitor (PPI), should be considered before invasive studies. Diagnosis of GERD may be delayed in individuals with ASD who do not localize pain or provide the classic history. PPI medications should be given 30 min before the first meal of the day, and if two doses are prescribed, 30 min before the evening meal. Assessment of response to a PPI trial is somewhat subjective in children with ASDs and might depend on changes in

behavior as perceived by care providers (parents, teachers, or health care providers). If further diagnostic testing is pursued, upper gastrointestinal radiographs can be challenging for many children who are unable to cooperate with drinking barium and lying down quietly for the procedure. Because of these potential barriers, it can be difficult to identify anatomic abnormalities, such as a malrotation, annular pancreas, or antral inflammation or narrowing, that may be the cause of GERD-like symptoms. Most children with ASDs are unlikely to tolerate placement of a transnasal pH probe for a prolonged period. A Bravo pH monitoring system (Given Imaging Ltd., Yoqneam, Israel), which is endoscopically attached to the distal esophagus, may be better tolerated. For such children, upper endoscopy under general anesthesia is often the diagnostic test initially used and might provide information about other gastrointestinal conditions such as carbohydrate malabsorption or food allergy or intolerance. Endoscopy is usually reserved for children who are unresponsive to a diagnostic trial of gastric acid suppression or when other clinical factors, such as hematemesis or food refusal, support the scheduling of invasive tests.

Treatment of GERD depends on the cause. Surgical therapy should be considered with a diagnosis of anatomic abnormality such as malrotation, whereas esophagitis may be treated best by prolonged acid suppression. Subsequent evaluation depends on the resolution and recurrence of an individual's symptoms. Upper endoscopy should be considered to follow children with long-standing GERD who may be at risk for developing complications such as esophageal stricture, Barrett esophagus, and esophageal cancer. As in children without ASDs, GERD in children with ASDs can be a chronic problem, with waxing and waning of symptoms. The management of such children often requires continuity with advancing age and an appreciation by the health care team of the natural history of disorders that underlie GERD (Vandenplas et al. 2009).

Sleep and Gastrointestinal Disturbance

Sleep disorders are among the many comorbid conditions present in ASDs (Lai et al. 2014). An

important point to consider is that sleep problems may be exacerbated by or even be the result of, other comorbid conditions. Other comorbid disorders in children with ASD are quite prevalent. In a population of over 160 children with ASD, Liu et al. observed attention deficit hyperactivity disorder (31%), epilepsy (11%), asthma (17%), allergies (50%), and gastrointestinal (GI) symptoms (21% with vomiting, reflux, spit-ups, 17% with chronic diarrhea, 18% with chronic constipation, 18% with abdominal pain, and 14% with intestinal bloating) (Liu et al. 2006). Although the mechanism of these sleep disturbances is difficult to ascertain, nighttime awakening with pain or abdominal discomfort is common with gastroesophageal reflux and reflux esophagitis in children. Autistic children with GI symptoms have been found to have a higher prevalence of sleep disturbances, compared with those in the general population who do not have GI symptoms and with their siblings. Furthermore, GI symptoms have been significantly correlated with insomnia and parasomnias. Taking into account that GI problems may be responsible for a great deal of sleep problems, one should consider that treatment focused on these conditions may bring relief or at least improvement in sleep problems symptoms. Lifestyle modifications, including smaller but more frequent meals or elevated head position during sleep should be considered as possible first-line treatments. Other approaches that should be taken into account whenever a child with ASD presents with sleep problems include, but are not limited to, proton pump inhibitors for gastroesophageal reflux or diet elimination/substitution therapies in food allergy such as cow milk protein allergy, lactose intolerance, or celiac disease. Naturally, of paramount importance is adhering to medical indications for introducing these treatments by way of proper diagnostic tests (Klukowski et al. 2015).

Future Directions

Medical disorders, including gastrointestinal problems, occur commonly in individuals with ASDs. Because the symptoms may be atypical,

these medical conditions may be undiagnosed. Whether the prevalence is higher than in the general population is not known with certainty. Prospective, well-controlled studies are necessary. Many parents and care providers have observed and reported improvements in problem behaviors with nutritional or medical interventions to address gastrointestinal symptoms and disorders. Some of these therapies are based on purely observational reports. The care of individuals who are nonverbal or have difficulties in communication or who display self-injurious or other problem behaviors presents special challenges. Nevertheless, the approach to evaluation and diagnosis of possible underlying medical conditions, in particular gastrointestinal disorders, should be no different from the standard of care for persons without ASDs. Management of gastrointestinal problems in individuals with ASDs usually begins with the primary care provider and may warrant consultation with a gastroenterologist and other specialists. Anecdotal reports that restricted diets may ameliorate symptoms of ASDs in some children have not been supported or refuted in the scientific literature, but these data do not address the possibility that there exists a subgroup of individuals who may respond to such diets. Professional supervision of restricted diets is recommended to prevent nutritional inadequacies (Buie et al. 2010a). Such reports help propagate interest in the use of dietary manipulation (e.g., gluten and casein-free diets) as an ASD-focused treatment. Dietary interventions, including the gluten- and casein-free diets, nutritional supplements, enzymes, and antimicrobial agents, have not been substantiated by empirical investigation, presenting a clear need to investigate how possible deviations in the GI tract in ASD relate to current dietary recommendations being promoted and implemented in the ASD community (McELhanon et al., 2014).

One should also consider possible deviations in the establishment and maintenance of the gut microbiome in ASD and the relative contribution of early feeding practices to overall gut health and acceptance of new feeding tastes and textures. Studies of fecal DNA extracts have found certain bacterial clusters overrepresented in children with

ASD and gastrointestinal complaints compared with children with similar GI complaints but typical neurobehavioral development (Mulle et al. 2013). Provisional evidence also suggests that children with ASD are at greater risk for suboptimal breastfeeding, including late initiation and shorter duration of exclusive breastfeeding (Al-Farsi et al. 2012). In addition to promoting optimal nutrition, breast milk assists in the development of the gastrointestinal tract, pancreas and endocrine system, and related mucosal defenses, and it is therefore possible that suboptimal breastfeeding may result in atypical colonization of the gut microbiome in ASD. In turn, changes in the gut microbiome may help explain anecdotal reports of improvement in behavioral functioning in response to dietary changes if such changes serve a probiotic function and improve symptoms of irritable bowel syndrome (e.g., bloating, abdominal pain, flatulence) among certain children with ASD (McElhanon et al., 2014).

Microbiota is an emerging topic that has attracted several researchers to look for the possible connection between the GI microflora and behavioral abnormalities. Earlier report of deficient disaccharidase enzymatic activity in ASD children and GI symptom prompted investigations looking for intestinal mucosal microbiota involved in carbohydrate metabolism (Horvath et al. 1999). Abnormal carbohydrate digestion and transport and mucosal dysbiosis (imbalance in the intestinal microbial ecosystem) was reported in the ASD children (Williams et al. 2011). Reduced level of fermenters has been found in the intestinal microflora of the ASD patients. The microbiota-gut-brain axis refers to the ability of gut microbiota to communicate with brain and regulate behavior. Fecal microbiota transplantation has been used in treating several GI disorders but increase knowledge and control trials are needed before it can be used broadly in clinic. Imbalance in gut microbiota population may render the intestinal mucosa susceptible to injuries, infections, inflammation, abnormal digestion, immune imbalance, immune reaction and cross reaction in other tissues including the brain. More research is emerging in this area (Samsam et al. 2014).

Future research is expected to clarify the role of metabolic disorders, allergic/toxic reactions, immune dysregulation, and inflammatory changes in the etiology of gastrointestinal disturbances in individuals with ASDs. Whether unique genetic, metabolic, or physiologic conditions exist and are specific to ASDs remains to be determined. New knowledge in these areas will advance our approach to the management of ASDs. Recognition that problem behaviors might indicate an underlying medical condition will facilitate diagnosis and treatment and ultimately improve the quality of life for many persons with ASDs. Well-designed trials are needed to develop an evidence base for optimal diagnostic and treatment strategies to manage gastrointestinal disorders in children with ASDs. Until then, application and, where necessary, adaptation of conventional recommendations for the general pediatric population are relevant to children with ASDs (Buie et al. 2010b).

GAUTENA Autism Society

Amaia Lopetegui

GAUTENA, Donostia, Gipuzkoa, Spain

Background and Context

GAUTENA is the acronym in Basque language of Gipuzkoa Autism Society www.gautena.org. This society of families of people with autism spectrum disorder (from now on referred to as ASD) was founded in 1978, in Gipuzkoa, one of the three provinces that constitute the Basque Country (Spain). In compliance with its Statute of Autonomy from 1979, the Basque Country has full

capacity and responsibility in areas such as Health, Education, and Social Services. This circumstance, together with the financial autonomy that the mentioned political regime confers to the Basque region, helps to understand GAUTENA’s development in favor of people with ASD in Gipuzkoa, a region of 1909 km² with a population of about 710,000 inhabitants.

The Basque Country, traditionally an industrial region and most recently focusing on the services sector, enjoyed in 2016 a per capita income of 31,805€ (10% higher than the average of the EU 28). The social protection expenditure per person, measured in purchasing power parity (PPP), was 8.341€, while the average of the UE 28 amounted to 7.903€. In terms of the UN Human Development Index that takes into account life expectancy, education, and wealth, the Basque Country is placed in the eight position in the world (0.91)

just next to the USA (0.92), although it is not fair to compare specific regions with full countries.

Landmark Contributions

Based on the previous work of other associations of families involved with disabilities and keeping a good relationship with them, GAUTENA began to work in 1978 with the purpose of achieving a community-based network of services for people with ASD within a society that pursues to be more inclusive every day. It currently provides support to 800 families and has a staff of about 230 members. Although the families pay some fees for the provided services, financing is mainly public (92%). In the last years, several laws at state and community level have reinforced the role of social services in the society.

Through different formal agreements with the Public Administration in the areas of Education, Health, and Social Services, GAUTENA encourages and manages a network of services that offer comprehensive support throughout the whole life cycle to people with ASD, such as diagnosis and treatment services, education, day services, sheltered housing, temporary stays, leisure, and support to families.

The key characteristics at the time of identifying GAUTENA's reality are the application of a suitable community-based model, the significant level of public support, the social sensitivity in our territory encouraging this kind of initiatives, and a nonprofit management. The organization is based on the pillars of quality-oriented practice, an ethical framework with empowering for human rights and personalization, and research and social innovation, in order to adjust the model to the changing needs of people with ASD. Based on these pillars, the main goal is the continuous fostering of a good quality of life for the users and their families and a more comprehensive and inclusive community for all.

Major Activities

Services Network

Through formal agreements with the Public Administration in areas of Education, Health, and Social Services, GAUTENA manages a service network that includes diagnosis and treatment, education, day services, housing, temporary stays, leisure and free-time activities, as well as support to families. More detailed information is given below.

Diagnosis and Treatment

The clinical team, which includes professionals of psychiatry and psychology, is in charge of the diagnosis and treatment of the people with ASD referred to GAUTENA from the Public Administration, mostly from the National Health System. In collaboration with the families, the GAUTENA team gives support through individual or group treatment sessions to more than 500 children and also offers specialized support for their schooling.

Education

The Public Administration policy in the Basque educational system strongly encourages and supports inclusion of students with special educational needs. For this reason, a good number of people with ASD – over 400 – supported by GAUTENA usually attend regular schools where they receive different levels of individualized support. Some of these students attend lessons in classrooms managed directly by GAUTENA, 19 classes at present, located in different districts of Gipuzkoa. In these classrooms, called “stable classrooms,” an average number of five students receive the support of two teachers. In such classrooms, the personalized mainstreaming of the students with ASD into the school is encouraged. At present, there are 98 students who attend these GAUTENA classrooms, located in regular schools (a special school we had was voluntarily closed years ago). The educational period extends from the age of 3 to the age of 20 with the possibility of an extraordinary extension up to 21.

Day Service

At the end of their school period, after they have reached the age of 20, people with ASD can access a well-developed sheltered employment organization, where GAUTENA sits on its Board, or try a supported job in the ordinary market. Up to the present time, it has been found that most of the people with ASD with from medium to severe affectation reaching adulthood turn toward the Day Service Centers managed by GAUTENA for day services. GAUTENA's four Day Centers offer a suitable combination of work on personal and vocational skills, together with a wide use of community-based resources that make possible to enjoy a good day program for about 112 adults with ASD in Gipuzkoa.

Housing Service

GAUTENA offers different types of housing to those who request this service, ranging from flats in blocks (Sheltered Flats) to small dwelling units (Group Homes) for people who need more structured support. This housing network includes one house for temporary stays extending the coverage

through different ways – weekends, short stays, critical periods, medium-period stays, etc. – to a significant group of families, children, teenagers, and adults. At the present time, 14 housing units provide permanent support to 78 people, and another house is used for temporary stays for around other 50 families.

Family Support Service

This service focuses directly on the families of people with ASD and offers them a wide range of support services, from family welcoming programs to the organization of support groups, training conferences and seminars, and leisure activities for families with their children with ASD. Also navigating the necessary processes to obtain economic subsidies, among other administrative benefits, is supported. This service involves and trains volunteers, usually university students, who may become staff persons later on. The Family Support Service organizes the leisure and free-time activities carried out by GAUTENA throughout the year and especially during the holiday periods, an initiative that involves more than 500 users.

Approach to Quality

GAUTENA is an organization inspired in community-based models, having paid since it's beginning a great deal of attention to the quality of services provided to the person with ASD. Based on technical criteria inspired in the most reputable international programs, since the middle of the 1990s, it has been working in compliance with the Quality Assurance criteria of ISO 9001 Standard, having received the pertinent accreditation from the Spanish Organization for Standardization (AENOR). In 2000, GAUTENA received a pilot accreditation from the National Autistic Society (UK) www.nas.org.uk. In 2008, GAUTENA received the Silver Q to Management from EUSKALIT (Basque Foundation for Excellence www.euskalit.net) for having obtained more than 400 points in the application of the EFQM model (European Foundation for Quality Management www.efqm.eu). Besides, GAUTENA enhances its work in favor of quality with other approaches such as that of “The Council”

www.thecouncil.org (USA) or that of Plena Inclusión/FEAPS www.feaps.org (Spanish Confederation in favor of People with Intellectual and Developmental Disabilities). In 2016 GAUTENA was granted by the European Parliament one of the European Citizen Awards for “having transformed the European values into support programs for the people with ASD.”

Looking at the Future

The Quality approach taken by GAUTENA starts from the response to the rights of people with ASD by guaranteeing a coherent ethical approach in a personalized plan, with the purpose of fostering quality of life for people with ASD and their families.

For that purpose, GAUTENA is developing instruments for the practical promotion of the rights of the people to whom support is given and especially for those that, because of their significant needs, almost whole responsibility is taken up by the staff. At the same time, an Ethical Adequacy Plan prepared in collaboration with the University of Deusto www.deusto.es (Bilbao and San Sebastian) is being applied, in order to embed ethics into the philosophy and practice of professionals and families in GAUTENA.

While developing rights, ethics, and quality of life, GAUTENA is giving as much support as possible to initiatives in research of ASD and has collaborated with important international entities. An agreement with the Research Foundation Policlínica Gipuzkoa Fundazioa, in San Sebastián, has been established, and it is taking part in research projects on genetics, phenotyping, immunology, epidemiology, and the use of augmentative communication devices www.policlinicagipuzkoa.com. In the frame of this agreement, GAUTENA is currently part of the ASDEU project, sponsored by the European Commission, involving over 10,500 children in its county.

In addition, social innovation, understood as the advance of innovative responses to the needs of people with disabilities, guides GAUTENA's steps and makes it to take part in general activities such as the one of the Basque Innovation Agency (Innobasque) www.innobasque.com. GAUTENA applies a policy of encouragement of

benchmarking and alliances, both in its most immediate area in Gipuzkoa and Basque Country, as well as in Spain and Europe, and it is an active member of several organizations, being a founding society of Autism Europe www.autismeurope.org.

Gaze

Rechele Brooks

Institute for Learning and Brain Sciences,
University of Washington, Seattle, WA, USA

Definition

Following the eye gaze of other people is a crucial component of face-to-face social interactions from infancy to adulthood. The ability to follow where a person looks is usually called “gaze following” or “responding to joint attention.” This and other gaze behaviors are important because they are powerful learning mechanisms. Specifically, research has shown that gaze following and other gaze behaviors predict language development for children with and without autism (Brooks and Meltzoff 2008; Mundy et al. 2007; Toth et al. 2006; Wetherby et al. 2007). In addition, the patterns of use and perception of gaze may help identify which at-risk children develop autism spectrum disorders (Jones et al. 2014).

There are several eye gaze behaviors that are widely studied, including mutual gazing, cued gaze shifting, gaze alternating, and gaze following. Each of these gaze behaviors has potential functions in early development. Special attention is paid to relevant findings for young children with autism spectrum disorder (ASD), as well as for infants at risk for developing ASD because their sibling has ASD. This entry uses gaze following to illustrate developmental changes in infants’ understanding of eye gaze.

Gaze following is an interesting developmental phenomenon because it provides a window into infants’ social cognition. Adults typically understand a person’s gaze in a way that puts them in touch with the other person’s mind, informing them of the other’s desires, emotions, intentions, and perceptions. When adults notice where someone is looking, they do not simply track the movement of the head and eyes; rather, adults understand that people use their eyes to see things of interest in their surroundings. In that sense, developmental scientists consider gaze following an important front-end ability that feeds into the development of understanding other minds (see entry on “► [Theory of Mind](#)”). For example, a mother could look with a disgusted facial expression at an object while saying, “I don’t like that.” For adults viewing this act, they can follow her gaze to find out what has caught her attention and what she is talking about, as well as what disgusted her. Individuals who do not follow gaze would miss this important social and referential information. This is of particular concern for children with ASD because they have developmental deficits in following the gaze of others, and this may contribute to other downstream problems in social understanding (Mundy et al. 2009; Jones et al. 2014; Toth et al. 2006).

Current Knowledge

As soon as infants are born, they are introduced to social interactions. At first, parents and infants share face-to-face eye contact in the *dyadic* context. Later, the social interactions become *triadic* when the dyad includes a third entity,

such as when an infant shifts her gaze between a parent and an object. The questions for developmental psychologists are when do infants begin to follow the gaze of other people and how do infants interpret others' eye gaze.

Gaze behaviors could indicate that both adult and child are aware that they are sharing attention. Indeed, triadic social interactions are often referred to as joint attention because the adult and the infant attend to the same topic. However, it is unclear whether young infants and children with ASD are aware that they are sharing attention and intentions. This has led to an ongoing debate in the field about how to interpret early gaze behaviors, especially gaze following (Flom et al. 2007; Mundy et al. 2009). On one side of the debate, infants gaze follow because they already understand that people can make psychological contact with external objects, that people see something interesting. On the other side of the debate, gaze following occurs for lower-order physical reasons, simply because of the signal value of the other's head movement. According to this latter perspective, infants do not understand anything about the adult as a perceiver of objects, but simply process the movement shown by the head. This ongoing debate has fueled extensive research on the emergence and meaning of gaze following.

Another important issue is the developmental outcome for children who have little or no interest in attending to the gaze of other people. This is a common concern of parents of children with ASD. A significant question is whether children with ASD notice the gaze of others and whether they interpret it as having psychological meaning. In order to answer this question, it is important to make conceptual distinctions among different types of closely related behaviors that are sometimes confused in the literature about gaze processing. As described below, there are crucial logical, developmental, and clinical distinctions among them.

Interest in Eyes and Mutual Gaze. Mutual gaze – staring directly into the eyes of another person – is one of the earliest experiences people have. It is a context for sharing emotions and communicating. Social partners recognize that

they are looking at each other. The developmental question is whether infants recognize that others are looking at them. It is known that young infants have preferences for face-like patterns containing eyes or eyespots (Johnson et al. 2008). For example, newborns look longer at faces with eyes facing toward them than eyes averted to the side. By the age of 2 months, infants begin scanning the eye region more than the edges of the face. These early patterns could stem from perceptual biases and preferences, but they are not clear evidence for noticing the eyes or recognizing eyes as having social and communicative intent.

Detecting cues of mutual gaze may be difficult for individuals with ASD. As an interesting test, Elsabbagh and colleagues (2012) presented gaze cues that contrasted eyes shifting to the side versus looking straight ahead to simulate looking away versus making eye contact. When infants (6–10 months old) viewed such cues, the infants with a subsequent ASD diagnosis were less sensitive on neural measures to the gaze shifts than infants without a later ASD diagnosis. In addition to difficulties with detecting mutual gaze, children with ASD often scan faces and eyes differently than children with typical development (Nation and Penny 2008). Decreased scanning of eyes may emerge as early as 6 months of age (Jones and Klin 2013). Across ages, children and adults with ASD are often interested in the mouth, yet they do not completely ignore the eyes (Webb 2008). An overall concern would be that reduced attention to eyes could lead to less experience with the socially meaningful information that eyes convey.

Peripheral Cue with Gaze Shifts. Another line of eye-gaze research investigates whether gaze shifts influence the attention of observers. To address this issue, gaze shifts are used to cue the location of peripheral targets, such as a rectangle or an asterisk (Johnson et al. 2008; Nation and Penny 2008). The classic stimulus with this task is a digitized face with eyes that shift to one side before a target appears on the right or left. The face usually vanishes before the peripheral targets appear in this paradigm. Adults and infants typically look with shorter latencies to the target that has been cued. If the cue shifts to

the right side, they attend to a target that appears on the right faster than on the left.

These are fascinating effects, but they do not provide evidence about following gaze in biologically plausible settings. In the real world, when a mother looks at and labels an object (“There’s a ball!”), her face does not vanish to free up attentional resources for the child. Moreover, the peripheral targets do not pop into existence to attract attention as they do in the cueing paradigms. Rather, in everyday settings, the world stays stable and the parental gaze spotlights a preexisting object. Nonetheless, infants’ responses to directional shifts in cueing studies may be a precursor to actual gaze following.

For individuals with ASD, the key question is whether they respond to gaze cues. In many but not all studies, the direction of the gaze shifts cued the reactions of children and adults with ASD (Nation and Penny 2008). For example, at 2 years old, toddlers with ASD responded faster to locations cued by gaze shifts than non-cued locations, which was similar to typically developing toddlers (Chawarska et al. 2003). Of interest with this study, the 2-year-olds with ASD on average “passed” this test of cueing, but they failed to follow a person’s gaze in a real room. Thus, the cueing phenomenon is not necessarily correlated with what individuals do in ecologically valid settings, which suggests that calling this “gaze following” would be a misnomer.

Gaze Cues in Habituation Studies. A third body of work that addresses infants’ reactions to gaze cues is habituation studies. In the first phase of a prototypical habituation study, a person looks at one of two objects. The trials are repeated until there is a decline in infants’ looking at the presentation (i.e., habituation). In the second phase, infants’ looking times are measured to examine which of two types of presentations attracts renewed interest (i.e., dishabituation). For example, Woodward (2003) found that infants, who habituated to a person looking at a ball on the left, dishabituated more strongly to that person looking at a bear on the left (new object, same location) than to that person looking at the ball on the right (same object, new location). This suggests that infants encoded the relationship

between the looker and the object, and that they dishabituated when the link was broken. The findings also showed that there is a developmental change for encoding this looker-object link, as seen by 12-month-olds succeeding in the task and younger infants failing. A consideration is that these habituation-dishabituation studies chiefly document infants’ recognition abilities. Infants recognize (and encode) that the other person is looking, but they are not required to produce an action to follow that person’s gaze.

To date, there are no parallel studies of gaze with habituation for children with ASD. It would be interesting to examine whether children with ASD encode the looker-object link. Further, does a child’s ability to spontaneously follow a person’s looking behavior in a real situation influence the habituation test (or vice versa)?

Gaze Alternation and Joint Engagement. Joint engagement refers to when infants and caretakers attend to and play with the same toy. This also is called a triadic interaction because the child and the parent communicate about a third object, such as a toy. Adults are aware of shared or joint attention in the triad, but an interesting question is whether infants are aware of it. An argument has been that infants show their awareness of joint attention by initiating eye contact with the adult and shifting their gaze to the toy. This type of gaze alternation is called “coordinated joint engagement” (Adamson et al. 2009). From observations of parents and infants at play, in the majority of joint play, infants did not alternate their gaze between the parent and a shared toy. Nonetheless, there were some instances of gaze alternation by the infants. The general pattern is that coordinated joint engagement emerges at about 9 months when it is relatively infrequent and brief, but gradually becomes more frequent and lasts longer, by 15–18 months, for typically developing infants (Carpenter et al. 1998).

Because of the importance seen in these gaze behaviors, researchers have designed tasks to prompt and assess the capacity for alternating gaze (Mundy et al. 2007; Wetherby et al. 2007). In a typical version of the gaze-prompting tasks, an experimenter activates a mechanical toy that is not within reach of the child. In a longitudinal

study, Mundy et al. (2007) found that 9-month-old infants readily made eye contact with the experimenter and alternated gaze to toys in the context of gaze-prompting tasks. These gaze behaviors were key components of their measure of “initiation of joint attention” and did not significantly increase by 18 months of age. The findings with the gaze-prompting tasks suggest that infants are capable of alternating their own gaze in structured situations before they consistently do so during unstructured play. Of note, these tasks do not directly measure how well infants understand the gaze of others.

Studies show that children with ASD are less likely to alternate gaze in a triadic context than children with typical development. At 20 months, toddlers with ASD were less likely to shift their gaze from the adult to a toy (or vice versa) than comparison groups in gaze-prompting tasks (Wetherby et al. 2007). As seen in play observations, 30-month-old children with ASD had many opportunities for joint play with the support of their parents, yet they rarely had episodes of coordinated joint engagement (Adamson et al. 2009). Even at older ages, gaze alternation remains less frequent among children with ASD than their peers with typical development; this has been viewed as a fundamental problem for children with ASD (Mundy et al. 2009; Toth et al. 2006).

Following the Gaze of Others. A simple head turn takes on referential meaning when a person looks at something in the environment. Adults recognize this and turn to see what the other has seen. However, it is unclear whether young infants with typical development and children with ASD turn for that reason. In the typical gaze-following test, an adult looks at an object by turning and aligning his (or her) head and eyes with an object in the room, and in studies of “responding to joint attention,” the adult also points during the look (Mundy et al. 2007). Research has shown that infants turn in the direction of the adult’s head (and arm) movement, as early as 3–6 months of age under certain conditions, and that this following becomes more frequent between 12 and 18 months for typically developing infants (Flom et al. 2007; Jones et al. 2014; Mundy et al. 2007). The difficulty in

interpreting these findings is that as the adult turns toward a target, the adult’s large and salient head motion may draw infants in the correct direction without them processing the adult’s gaze at all. Infants may simply be following the head motion that they see in their visual field and find the target object by chance.

To test whether infants follow head motion or eye gaze, Brooks and Meltzoff (2002) designed a special test using a gaze-following paradigm. The key manipulation was that the adult turned toward an object with open eyes for one group and closed eyes for the other group. The test controlled for head motion because the adult made the same head motion for both groups – what differed was whether the adult’s eyes were open or shut. If infants relied on simple head motion, they would turn in the same direction as the adult in both cases. If, however, infants recognize that eyes are part of the referential act, they would turn to look at the target object in one situation but not the other. The results showed that 12- to 18-month-old infants were more likely to look at the adult’s target when she turned with open eyes than closed eyes. Infants did not simply follow head motion because they differentiated the head turns. Instead, infants followed the gaze of the adult to the target objects; infants from 12 to 18 months genuinely followed *gaze*.

The question remained as to when gaze following develops. To test for the emergence of gaze following, Brooks and Meltzoff (2005) used the same test of open versus closed eyes with 9-, 10-, and 11-month-olds. The findings suggested that genuine gaze following emerges at 10–11 months of age. At the two older ages, infants followed the adult’s head turns with open eyes more often than turns with closed eyes. In contrast, 9-month-olds looked at the target object in both cases, for eyes open *and* closed. The 9-month-olds “failed” to follow gaze – they followed the adult’s head turns even when her eyes were closed. These findings suggested that young infants were following head motion rather than eye gaze.

With their lack of interest in eyes, will children with ASD follow a person’s gaze? It is unknown whether children with ASD follow eyes versus head motion because this particular empirical

test has not yet been done. However, in other gaze-following protocols, infants at risk for ASD have deficits that are detectable after 12 months of age (Jones et al. 2014). By 20 months, toddlers with ASD were unlikely to follow the line of regard of an adult, even though the adult looked and pointed at a target; their scores were lower than those of toddlers with other types of developmental delay or with typical development (Wetherby et al. 2007). By about 4 years of age, children with ASD are more likely to follow the adult's line of regard than younger children with ASD, but many children with ASD are still less likely to follow an adult's actions than peers with typical development (Mundy et al. 2009; Nation and Penny 2008).

Future Directions

There are several provocative issues left to resolve for gaze behaviors. How do gaze behaviors relate to one another (e.g., detecting mutual gaze and gaze following)? Does improving one type of gaze behavior lead to global changes in other gaze behaviors? What are the developmental steps that help infants and children understand the referential nature of looking and seeing? Does the difficulty that children with ASD have with an elementary behavior such as gaze following contribute to and predict their later deficits in understanding others' minds (i.e., theory of mind)?

Researchers have shown that interventions can prompt children with ASD to follow others' line of regard, but they have not examined whether children with ASD are specifically following eye gaze (e.g., Kasari et al. 2006; Schreibman et al. 2015). Future research can continue to explore best practices to help children with ASD develop an interest in eyes and follow the eye gaze of others. One suggestion is that infants' own experiences may help them learn. Infants and children may use their own visual experiences as a framework for understanding that behavior in others. When infants open and close their own eyes, they immediately change whether they can (or cannot) see their surroundings. This

experience could help them recognize the same effect of eye closure for others. In an experimental study for infants with typical development, infants' own experiences with visual obstructions changed how they interpreted another person's line of sight (Meltzoff and Brooks 2008). The findings suggest that infants' visual experiences change what they understand about looking. Will interventions designed to vary the visual experiences of toddlers and children with ASD help them learn to follow the gaze of others? This and other interventions that actively involve the infant or child may greatly advance developmental progress for children with ASD (Schreibman et al. 2015). The overall goal to improve children's gaze following is important because gaze following predicts language development, which in turn can help children understand the minds of other people (Brooks and Meltzoff 2015; Mundy et al. 2009).

GEC (Global Executive Composite)

► BRIEF (Behavior Rating Inventory of Executive Functions)

Gelotophobia and Autism

Geraldine Leader and Arlene Mannion
Irish Centre for Autism and Neurodevelopmental Research (ICAN), National University of Ireland, Galway (NUI Galway), Galway, Ireland

Definition

Gelotophobia can be defined as the fear of being laughed at. It comes from the Greek word “gelos,” which means laughter, and the word “phobia” meaning fear (Ruch and Proyer 2008a; Titze 2009).

Historical Background

Gelotophobia was originally derived from clinical case studies and introduced as a clinical

condition by Titze (1996, 2009). However, gelotophobia is not a pathology but is experienced in the typically developing population also (Ruch et al. 2014). Gelotophobia is an interindividual differences variable. At its extreme end, it may lead to a pathological fear, but only in rare cases of gelotophobia (Ruch and Proyer 2008a, b). Given the implications and consequences associated with gelotophobia, such as social anxiety and social withdrawal (Titze 1996, 2009), this is an important area of study.

The phenomenon of gelotophobia has not only been investigated in the typically developing population. Previous research has found that 40% of individuals with eating disorders exceeded the threshold for a slight form of gelotophobia, 35.7% of individuals with personality disorders experienced gelotophobia (Forabosco et al. 2009), and 24.6% of shame-bound neurotics showed gelotophobic tendencies (Ruch and Proyer 2008b).

Gelotophobia is of importance to study in individuals with autism spectrum disorder (ASD). Due to the deficits in social communication and social cognition, individuals with ASD may experience difficulties with empathy. This is a result of their reduced theory of mind capacity which hinders their ability to distinguish between one's own mental state and that of others (Woods et al. 2013). Individuals with ASD may have greater difficulty understanding and compartmentalizing their own emotions and conveying these emotions to others (Woods et al. 2013). Individuals with ASD may have difficulty in understanding nonverbal cues, reciprocal interaction, and initiating appropriate nonverbal communication (Frith 2004; Wing 1981). Individuals with ASD may also have difficulty understanding humor. Weiss et al. (2012) compared whether children with ASD could appreciate slapstick comedy in comparison to children who were typically developing. While children with ASD could appreciate the material, they had greater difficulties in discriminating humorous from non-humorous material. Given these reasons, gelotophobia is of relevance to study in individuals with ASD.

Current Knowledge

Samson et al. (2011) conducted the first study that investigated gelotophobia in individuals with Asperger's syndrome. Samson et al. (2011) investigated gelotophobia and its relationship with recalled experiences of having been laughed at in the past in 40 individuals with Asperger's syndrome and in 83 neurotypically developing control group participants. It was found that in individuals with Asperger's syndrome, 45% exceeded the cut-off of having at least a slight fear of being laughed at. This was in comparison to only 6% of control participants who exceeded this cut-off. There were statistically significant higher levels of gelotophobia found in the Asperger's syndrome group, compared to the control group. It was found that 17.5% of individuals with Asperger's syndrome had a marked fear of being laughed at, with a further 7.5% endorsing a severe fear of being laughed at. High levels of gelotophobia were found in individuals with Asperger's syndrome in comparison to control group participants, when both groups had a high frequency of recalled experiences of being laughed at. Therefore, recalled experiences of being laughed at does not explain why individuals with Asperger's syndrome demonstrated high levels of gelotophobia.

In control group participants, who were measured on the Autism-Spectrum Quotient, gelotophobia was positively associated with autism spectrum level, which demonstrates a relationship between gelotophobia and Asperger's syndrome. The percentage of those with Asperger's syndrome who presented with gelotophobia (45%) was the highest percentage reported in the literature at that time.

Samson et al. (2011) outlined a number of reasons as to why gelotophobia may be more common in individuals with Asperger's syndrome. First, individuals with Asperger's syndrome may have a higher frequency of situations where they were laughed at in the past. Second, individuals with Asperger's syndrome often lack social awareness and therefore may have difficulties understanding how to deal with someone laughing at them. Third, individuals with

Asperger's syndrome may have difficulty reading social cues and may not be able to differentiate between good-natured teasing and bullying. Samson et al. (2011) provided a novel area of research for autism researchers to address.

Following Samson et al. (2011), there has been only a small number of studies that have investigated gelotophobia in individuals with ASD. Samson (2013) conducted a literature review on sense of humor in individuals with autism spectrum disorders (ASD). While focused on humor, the literature review provided a valuable summary of the literature on humor in ASD and briefly discussed gelotophobia. Wu et al. (2015) investigated the role of parental attachment in relation to gelotophobia in adolescents with ASD. Participants were 101 Taiwanese high school students with ASD with average intelligence and in 163 typically developing students. Adolescents with ASD showed significantly higher levels of gelotophobia than those without ASD. A negative relationship was found between attachment to fathers and gelotophobia in the ASD group. Therefore, as the quality of attachment to their fathers increased, gelotophobia decreased. However, no relationship was found between maternal attachment and gelotophobia. Therefore, by increasing the quality of father-child attachment in ASD, this may have implications for the occurrence of gelotophobia (Wu et al. 2015). The authors suggested that future research should investigate the relationship between attachment to peers and gelotophobia.

Tsai et al. (2018) investigated the relationship between gelotophobia and personality traits in 123 Taiwanese high school students with ASD and in 156 typically developing students. The ASD group demonstrated higher rates of gelotophobia than the control group. It was found that 42.3% of individuals with ASD had some form of gelotophobia, with 4.9% showing extreme gelotophobia, 4.9% with marked gelotophobia, and 35.8% with slight gelotophobia. The personality traits examined were the Big Five: Extraversion, Conscientiousness, Agreeableness, Openness, and Emotional Stability. Extraversion was found to be a mediator of gelotophobia. Therefore, individuals who

showed lower levels of extraversion experienced more gelotophobia, as these individuals were less able to engage in humor with others. The authors suggested that these results may be applicable to participants from an Asian cultural background, and therefore, the results of this research need to be replicated across different cultures.

Grennan et al. (2018) conducted a literature review on the link between gelotophobia and high-functioning ASD (hfASD). In this review, the characteristics of gelotophobia were discussed, including the conceptualization and measurement implications of gelotophobia, the etiology and consequences of gelotophobia, and the social competence of gelotophobes. The importance of studying gelotophobia in hfASD was discussed, as well as the relationships between hfASD and other variables relevant to gelotophobia, including comorbid psychopathology, quality of life, social functioning, perceived social support, past experiences of bullying, and shame-bound emotions. This review demonstrated the need for further research to be conducted in the area and discussed the importance of better understanding the relationship between gelotophobia and comorbid psychopathology in individuals with ASD.

Following this, Leader et al. (2018) conducted an empirical investigation specifically on individuals with hfASD, where gelotophobia was examined in 103 adults with hfASD and in 137 typically developing control participants. Moreover, it was the first study of its kind to explore the relationship between gelotophobia and other psychosocial constructs and the presence of psychopathological disorders in individuals with hfASD. The study examined gelotophobia in relation to a number of other variables, including social functioning, perceived social support, life satisfaction, quality of life, past experiences of bullying, and comorbid psychopathology. Individuals with hfASD presented with high rates of gelotophobia (87.4%) compared to 22.6% of control participants. This was a higher rate of gelotophobia, almost double, than what was found in the results of the Samson et al. (2011) study. Significantly higher levels of gelotophobia and higher past experiences of bullying were found in those with hfASD, in

comparison to typically developing control participants. The hfASD group showed lower quality of life, life satisfaction, social functioning, and perceived social support, in comparison to the control group. Of the 84.7% of participants with hfASD who presented with gelotophobia, 34% demonstrated a marked form of gelotophobia, 29.1% presented with an extreme form, and 24.3% presented with a slight form of gelotophobia.

Leader et al. (2018) found significant negative correlations between gelotophobia and quality of life, life satisfaction, perceived social support, and depression and anxiety. A significant positive correlation was found between gelotophobia and personal involvement in bullying and social functioning. The predictors of gelotophobia were examined in Leader et al. (2018). Social functioning, past experiences of bullying, anxiety, and life satisfaction were identified as predictors of gelotophobia. It was found that past experiences of verbal bullying were a stronger predictor of gelotophobia than physical and indirect forms of bullying.

Future Directions

Given the small number of studies that have focused on gelotophobia in individuals with ASD, there is a need for future research to focus on a number of specific directions. First, other methodologies should be used other than self-report. Self-report may lead to incidences of social desirability among participants. Where research requires individuals to report remembered situations of past experiences of bullying, self-report can be compromised by age-related memory loss. Future research could also include interviewing instead of questionnaires, field observation, and the use of peer and parental reports (Wu et al. 2015). Samson et al. (2011) outlined that peer-reports by teachers or parents could be used to investigate the influence of prior experiences of being laughed at, and whether this affects the development of gelotophobia later in life. Other peer report could come from other individuals in

a person's life, such as siblings or employers, in order to encapsulate the influence of bullying exposure on gelotophobia. Second, more research is needed to determine the relationship between gelotophobia and other fears and phobias. Samson et al. (2011) suggested that future research should focus on gelotophobia in relation to the development of social phobia. Leader et al. (2018) found that the presence of an anxiety disorder diagnosis was a predictor of gelotophobia. This possible link between gelotophobia and anxiety needs to be examined in future research. Third, research is needed on ASD populations other than individuals with hfASD. Gelotophobia needs to be investigated across the autism spectrum, from individuals with more severe symptoms of ASD to those with milder symptoms. Fourth, the relationship between gelotophobia and ASD severity needs to be better understood. Samson (2013) outlined that if the relationship between humor and ASD severity is investigated in future research studies, a model could be designed to explain the connections between symptom severity and the domains of humor in individuals with ASD.

Fifth, given the negative consequences of gelotophobia, research is needed to determine how gelotophobia can be treated. Gelotophobia must first receive further empirical investigative work in order to support its prevalence and further determine its consequences, symptomatology, and consequences in individuals with ASD. This will in the future lead to the development of specific intervention and preventative strategies for its treatment. While literature exists on strategies to reduce bullying in ASD, empirical evidence is needed on the intervention of and prevention of gelotophobia in individuals in ASD. This treatment may include learning to differentiate between teasing and mocking, and strategies which may help individuals with hfASD to disentangle harmless teasing from hostile bullying (Attwood 2004). Sixth, research is needed on the use of the Picture-Geloph in individuals with hfASD. The Picture-Geloph is a semi-projective tool, piloted by Ruch et al. (2009) which involves 20 cartoons depicting social situations which

involve laughter or potential laughter. Whether these cartoons are interpreted in the same way by individuals with hfASD as they are by individuals in the typically developing population is a question for future research to determine. Seventh, gelotophobia needs to be investigated with children with ASD. A child version of the PhoPhiKat (Ruch and Proyer 2009) has been developed, which measures gelotophobia, gelotophilia (i.e., the joy of being laughed at), and katagelasticism (i.e., the joy of laughing at others). The child version has been used in previous research with typically developing children (Proyer et al. 2012). Research is needed to determine the validity of this measure in children with ASD.

Finally, research is needed to determine the relationship between gelotophobia and alexitymanias in individuals with hfASD. Alexitymania is the inability to express emotions and has been identified as being an issue in individuals with ASD (Costa et al. 2017; Fitzgerald and Bellgrove 2006). A link between gelotophobia and alexitymania has been discovered (Boda-Ujlaki and Séra 2013), yet future research is needed to empirically explore these concepts in individuals with hfASD. In conclusion, the area of gelotophobia and ASD is a novel field of autism research, where much more research is needed to expand our understanding of the concept of gelotophobia in individuals with ASD.

referred to as “sex differences”) between the sexes.

Historical Background

Kanner's earliest writings about autism highlighted the now frequently documented gender difference in the prevalence of the disorder (1943). These early case studies, of eight boys and three girls, described few other gender differences within the sample; the male and female children were described similarly with respect to their limited social reciprocity and communication functioning and atypical interests and repetitive patterns of behavior. Nevertheless, since Kanner's time, there has been much speculation that gender differences exist in the clinical presentation of ASD. These concerns have been raised in no small part because much of the research on ASD has used clinic and research samples with a predominantly or exclusively male composition (Lai et al. 2014).

Gender Differences

Marisela Huerta

Center for Autism and the Developing Brain,
Weill Cornell Medicine, New York, NY, USA

Definition

Gender differences in autism spectrum disorders (ASD) primarily refer to the behavioral phenotypic differences between affected males and females. Gender differences have also been examined with respect to the diagnosis and prevalence of ASD. Of note, the term “gender differences” is used here to describe socially defined as well as biologically defined differences (elsewhere

Current Knowledge

Researchers have proposed models of ASD that explain and predict gender differences such as Simon Baron-Cohen's “extreme male brain” theory which proposes that testosterone-driven differences in cognition are at the core of ASD (2005). Others propose a “female protective model”; this model states that females require larger genetic insults for ASD symptom expression and has found some support in genetic studies (Jacquemont et al. 2014). More recently, the concept of “camouflaging” has been used to explain the gender differences in ASD; the term is currently used in an interchangeable manner to describe a number of behaviors the use of compensatory strategies (Dean et al. 2017; Lai et al. 2017; Livingston and Happé 2017), the presence of an atypical cluster of symptoms (Kirkovski et al. 2013), as well as self-reported efforts to minimize or “hide” impairments (Bargiela et al. 2016;

Lai et al. 2017). However, despite the fact that there are very clear sex differences in the prevalence of ASD, the existing literature describes few differences in the behavioral and clinical presentation of ASD in males and females. The following are highlights of the work completed to date.

Current prevalence estimates place the overall male-to-female ratio of ASD at 3:1 (Loomes et al. 2017). In samples with moderate to severe intellectual disability, the male-to-female ratio decreases to 1.95:1, while in samples without cognitive impairment, the ratio is closer to 5.5:1 (see Fombonne 2005 for a review). There is also evidence that the male-to-female ratio in ASD is higher in “essential autism” (ASD with no significant congenital anomalies) than in “complex autism” or ASD associated with significant dysmorphology or microcephaly (Miles et al. 2005).

As with ASD prevalence, research studies have consistently found gender differences in cognitive functioning. Affected females, on average, have lower nonverbal and adaptive scores than males (Van Wijngaarden-Cremers et al. 2014; Frazier et al. 2014; Volkmar et al. 1993; Lord et al. 1982). Gender differences in language development merit further study. Overall, when compared to affected males, females demonstrate lower verbal ability and greater difficulties in the areas of language processing and comprehension (e.g.; Frazier et al. 2014; Konstantareas et al. 1989). In the area of pragmatic language skills, toddler girls demonstrate greater impairments than boys (Carter et al. 2007; Hartley and Sikora 2009); this gender difference is reversed in school-age samples (Conlon et al. 2019).

With respect to the core features of ASD, large-scale studies have been able to account for the effects of developmental factors (such as IQ and language level) and have found no gender differences in autism severity (Kaat et al. 2020; Tillmann et al. 2018). Similarly, gender differences have not been found in the social communication behavior of toddlers, children, and adults with autism (van Wijngaarden-Cremers et al. 2014). In contrast, studies that examine social

behaviors more generally find that female children demonstrate compensatory strategies (e.g., Dean et al. 2017) and present with relative strengths compared to males (Jamison et al. 2017; Head et al. 2014). Consistent with these findings, female children demonstrate fewer impairments than males on “higher-level” social communication items of the ADOS, behaviors that as a group are not specific to a diagnosis of ASD (Bishop et al. 2016). In this same study, no gender differences were found on items uniquely associated with ASD, those that assess basic social communication.

Various studies have identified gender differences in some aspects of restricted and repetitive behavior (RRBs). In samples of children, adolescents, and adults, but not toddlers, females with ASD demonstrate fewer RRB symptoms than males (Van Wijngaarden-Cremers et al. 2014). Recent studies reveal that this gender difference is found across all levels of functioning in RRB total scores of the ADI-R and RBS-R restricted interest scores (Frazier et al. 2014). Notably, RRBs described as “insistence on sameness” behaviors on the ADI-R do not appear to be predicted by gender (Hus et al. 2007; Richler et al. 2010). Qualitative examination of repetitive behavior in school-age children reveals further differences. Girls, as compared to boys, are less likely to engage in repetitive use of objects and more likely to demonstrate fixations, often on age-appropriate topics (Hiller et al. 2014).

In regard to the broader behavioral and psychological functioning of children and adults with ASD, results vary by developmental level and age. In a sample composed primarily of children and young adults with ASD and intellectual disability, males and females demonstrate similar levels of disruptive behavior, hyperactivity, and attentional difficulties (see, e.g., Brereton et al. 2006). In the Simons Simplex Study, comprised primarily of cognitively able children and adolescents with ASD, females demonstrate greater externalizing problems relative to males (Frazier et al. 2014) girls also show greater sleep problems, anxiety/mood, and emotional problems (Hartley

and Sikora 2009; Holtmann et al. 2007, Mandy et al. 2012). The findings with respect to attention problem and overactivity in children are mixed (Mandy et al. 2012; Frazier et al. 2014). In adolescence and adulthood, females diagnosed with ASD demonstrate greater increases in anxiety and depression (Gotham et al. 2015; Solomon et al. 2012). Self-report data also suggests such gender differences in mood disruptions, but not in anxiety (Lever and Geurts 2016).

Few studies have longitudinally examined gender differences in the core symptoms of ASD, and fewer still have included sufficient samples of females. Emerging research suggests that in early childhood, female children may demonstrate better trajectories than their male counterparts (Waizbard-Bartov et al. 2020). In adulthood, males and females present with similar clinical profiles (Howlin et al. 2004; Shattuck et al. 2007; Taylor and Seltzer 2010). However, when broader outcomes are examined (e.g., employment), there is evidence that adult females fare worse than males (Howlin et al. 2004; Taylor and Mailick 2014). Self-report from adult women with ASD further suggests that unique challenges arise when impairments associated with ASD intersect with cultural norms and expectations of women's behavior (Bargiela et al. 2016).

In sum, the existing body of research points to a clear gender difference in the prevalence ASD; the male-to-female ratio is estimated at 3:1, with a greater frequency of females at the lower end of cognitive ability. Taking together all of the currently available research, gender differences in the behavioral phenotype of ASD are subtle (e.g., qualitative differences in repetitive behavior) and reflect interactions among multiple factors (e.g., developmental level). At present, sex differences in social functioning are limited to broader areas of functioning that are nonspecific to ASD. Importantly, the current research on gender differences in ASD should be considered in light of the following: female children with ASD are less likely to have a formal diagnosis of ASD (Giarelli et al. 2010) and more likely to be diagnosed later than

their male peers (Begeer et al. 2013; McCormick et al. 2020).

Future Directions

While significant strides have been made in recent years to utilize large samples to examine differences between the male and female autism phenotype (see Kaat et al. 2020; Tillmann et al. 2018), further quantitative and qualitative examination of the gender differences in ASD in large and well-characterized samples of children and adults is needed. Important to this work will be our ability to identify other within-group differences in ASD (see Joseph et al. 2002; Miles et al. 2005; Lord et al. 2015; Stelios et al. 2017) and further refine our ability to assess the core symptoms of ASD across development and contexts (Anagnostou et al. 2015).

Definition

The term Gender Dysphoria (GD) is defined as a mismatch between the phenotypic sex of an individual and that person's perception of their biological gender (American Psychiatric Association 2013), and was previously defined as Gender Identity Disorder (American Psychiatric Association 2000; World Health Organization 1992). GD hereby used to describe Gender Identity Disorder (GID), and Gender Dysphoria (GD) is increasingly reported in ASD research.

Background

The term gender refers not to the sex one is born with but to the psychological identification of oneself as the traditional dichotomy female or male, but also as both, neither, or something else regardless of the physical attributes. The awareness of one's gender usually emerges around 18 months to 3 years of age. However, sometimes an individual's natal sex is not the same as their gender (George and Stokes 2017a). In DSM-5, the term "gender dysphoria" (GD) is used and van Schalkwyk et al. (2015) points out the difference in terminology from the DSM-IV,

where the diagnosis previously was named "gender identity disorder," which gave the impression that being transgender was a form of mental illness. There are still some concerns regarding the criteria in DSM-5 that the individual must experience a certain presence of distress to be diagnosed, which might result in individuals experiencing perhaps confusion, but not distress, not receiving proper help and guidance (van Schalkwyk et al. 2015). This process towards an acceptance of a more diverse view of gender identity and gender roles can be compared to the one of homosexuality, which was classified as a mental illness by the American psychiatric association until 1987 (Burton 2015). It is estimated that between 0.005–0.014% of all natal males and between 0.002–0.003% of all natal females would have been diagnosed with GD following current diagnostic criteria (George and Stokes 2017b). GD can, for instance, be expressed by a wish to dress in clothes typically worn by the opposite sex (defined by that individual's cultural norms), adapting to cross-gender norms, and typical thought patterns related to the opposite sex.

Current Knowledge

There has been increased attention towards individuals with ASD who also express gender-related issues in the past years, and both case reports and systematic studies have been published showing that it is apparent that there is some overlap between ASD and GD (George and Stokes 2017b). A Dutch study (De Vries et al. 2010) looked at the rates of ASD in 204 children and adolescents referred to a gender identity clinic, finding that 7.8% ($n = 16$) of them were thought to qualify as having ASD. Of these individuals, one in seven children had persistent GID (they used DSM-IV, which is more inclusive concerning criteria compared to ICD-10). Five of nine adolescents met criteria for GID, and the remaining met the criteria for Gender Identity Disorder Not Otherwise Specified (GID-NOS) or transvestic fetishism, leading the authors to conclude that ASD is more common in GID individuals (De Vries et al. 2010). van Schalkwyk et al.

(2015) points out that this conclusion might be more correctly rephrased as “ASD is more common in individuals with a broad range of gender-related concerns or questions” (van Schalkwyk et al. 2015). They also suggest that gender-formation in children can be seen as a process in development, where children reflect upon their identity through and by their gender and eventually forming an idea of this. However, due to large variations in cognitive and social development in children, this might be difficult to quantify by age-groups in research. This concept of gender-formation in childhood as a process with many possible outcomes is supported by research, where children with GD were followed up 10 years later, showing that only 27% of the individuals still qualified for a GD diagnosis. The majority of the non-GD individuals had instead developed a non-heterosexual identity. This indicates that gender identity and sexuality in some children are fluid concepts that later in puberty tend to crystallize into a more “final” form. ASD children display different patterns in social development, so this development of gender- and sexual identity might take on other forms or time perspectives, compared to TD children (van Schalkwyk et al. 2015). It is clear that co-occurrence of ASD and GD can lead to significant confusion, distress, and difficulties for the affected individual, primarily if the individual is not supported and guided. Therefore, it is essential for clinicians, health personnel, school teachers, and relatives to be informed and prepared to help and guide ASD individuals and to be aware of the increased possibility of confusion and uncertainty regarding their gender identity and sexuality already from an early age.

Pasterski et al. (2014) examined the co-occurrence of GD and autistic traits in an adult population with a confirmed diagnosis of transsexualism. To measure autistic traits, the Autism Spectrum Quotient (AQ) was administered. It is a self-administered questionnaire designed to measure where an individual lies on the spectrum, from normal to autistic. It uses a Likert scale comprised of five scales: social skills, attention switching, attention to detail, communication, and imagination. A person who scores high on the AQ scale are often not very skilled at social interaction, have an

unusual ability to focus, but struggles with switching attention, have an eye for details but lacks imagination, traits prevalent among individuals on the spectrum. Their results showed that 7.1% in Female to Male (FtM) and 4.8% in Male to Female (MtF) individuals scored above the estimated threshold for a potential diagnosis of autism, a clear average above the prevalence in the general population. The result that there were no significant differences in the co-occurrence of ASD and GD between natal females and males differs somewhat from other reports. Other studies have found that there’s a higher ratio of natal males in childhood who present with ASD and GD diagnoses, separately (Pasterski et al. 2014), and in the similar study by Jones et al. (2012) where they compared FtM and MtF transsexuals and found that the FtM group displayed a higher mean AQ than control groups of both sexes and the MtF group. They suggested that the Extreme Male Brain (EMB) theory might explain autistic traits as a part of a masculinized phenotype in FtM transsexuals.

A recent study examined the relationship between GD, ASD, and sexual orientation by looking for GD traits, and not the diagnosis, in a population of individuals diagnosed with ASD. They further hypothesized that GD traits would have a mediating effect between sexual orientation and ASD traits (George and Stokes 2017b). Their results concluded that the earlier seen association between GD traits and autistic traits also is true the reversed direction. Autistic individuals score higher on the GD scale than the typically developing control group, indicating that there is a bigger gender-variance in an autistic population. Autistic persons born as women only differed from those borne as men only on one of the subscales. Levels of GD traits were significantly higher among all other sexuality groups (homosexuality, bisexuality, asexuality, and other) than heterosexuality, and by heterosexuality, the authors refer to being attracted to the opposite of one’s natal sex. The EMB theory is also discussed here, with similar conclusions as mentioned earlier that high levels of fetal testosterone (fT) to some degree might explain the heightened rate of GD in ASD females, by shaping the individual in a masculine way. However, this reasoning does not explain the same heightened

rates of GD in males with ASD (George and Stokes 2017b).

The internet has made explicit sexual material available for the public, and there are countless of other sources that we are daily exposed to, providing different messages of relations, sexuality, norms, and ideals (George and Stokes 2017b). These changes have also sparked new life into the research on sexuality, and also on the topic of autism and sexuality. Flirting, courting, and relationships are activities that many typically developing (TD) individuals find challenging at times, and with an ASD where one of the most prominent traits concerns difficulties in the social domain, this can prove especially challenging. There are not a plethora of studies on autism and sexuality, and the few have been conducted on institutionalized, autistic male individuals with varying cognitive abilities living in group homes. These individuals were often reported engaging in more or less problematic sexual behavior, such as masturbating in public and inappropriate removal of clothes in front of others. Important to note though is that the studied subjects might have influenced the results from these studies and may not be representable for so-called “high functioning” autistic individuals living successfully as a part of society (George and Stokes 2017b). It is worth noting though that these most studies have had small- and gender-atypical male samples might have obscured more correct tendencies (Gilmour et al. 2012). The study by George and Stokes (2017b) found higher rates of asexuality in ASD individuals compared to TD but speculate that there might be several reasons for this. It is not uncommon for ASD individuals to experience sensory issues, hypersensitivity, tactile defensiveness, and other physical obstacles and might also find social interaction challenging. These factors might make lead to a decision of celibacy, even though it necessarily doesn't mean that the individual lacks feelings of sexual desire. Males and females with ASD also reported higher rates of bisexuality compared to their sex-matched TD group, supporting the finding by Gilmour et al. (2012). Several participants expressed that either heterosexual or homosexual sexual identity did not describe their identity correct but suggested others such as asexual, intersexual,

transsexual, and “other.” George and Stokes (2017b) discuss the EMB theory and points out that higher than usual levels of fT among males could be expected to lead to a hyper-masculinized individual resulting in heterosexuality. There is no convincing evidence for this connection. Some studies find this to be the case, and others have found opposite results where male ASD individuals have more homosexual tendencies, some found no relationship, and other studies again have found a relationship between lower fT and higher homosexuality. It is clear that there is no consensus on how fT affects the sexuality of males.

Future Directions

The field of autism spectrum disorders (ASD) and gender dysphoria (GD, here also includes GID) have seen a massive increase in research on this somewhat rare co-occurrence over the past decades. Notably, a considerable rise can be found in studies published in scientific journals over the past 3–4 years (Øien et al. 2018). This increased interest in gender dysphoria, trends, and patterns could explain sexuality and ASD we see elsewhere in the society, where sexual attitudes that previously were taboo is receiving increasing acceptance, and the empowering of the LGBT movement has also been seen. Furthermore, it is likely that the technologies such as social media and easier access to relevant information and internet communities have affected and inspired individuals to be open about their sexuality and provided them with a way of interacting and discussing their difficulties with someone in the same situation. While we do see a significant improvement in attitudes and acceptance for sexual minorities, there is still a long way to go before we meet a global improvement for all of these sexual minorities. Most studies are conducted in liberal Western countries, and little is currently known about the co-occurrence in more conservative countries where, e.g., homosexuality is still highly taboo.

Besides from the demand for more studies from other cultures, the most prominent difficulty for the field of GD and ASD research is

the fact that the co-occurrence is rare, and thus very few individuals are to be recruited to studies.

Gene Regulatory Networks in Autism

Melody Oliphant and Thomas Fernandez

Yale Child Study Center, Yale University School of Medicine, New Haven, CT, USA

Structure

Findings from genetic studies of autism spectrum disorder (ASD) reflect a central divergence as to whether the majority of genetic risk arises from common variation that is frequent but with low penetrance, or from rare variation with a high degree of penetrance and large effect. ASD is characterized by a high degree of both genetic and phenotypic heterogeneity. Despite long-standing evidence that ASD is a highly heritable, polygenic disorder, there still remains some uncertainty about the full allelic spectrum that underlies ASD.

With the advent of next-generation sequencing technologies, researchers have focused on the contribution of de novo variation through whole exome sequencing (WES) studies and genome-wide genotyping arrays to identify rare single nucleotide variants (SNVs), insertion-deletions (indels), and copy number variants (CNVs) associated with ASD. The identification of such variation in ASD-diagnosed individuals has resulted in the discovery of dozens of definitive ASD risk loci and genes over the past decade (De Rubeis et al. 2014; Dong et al. 2014; Iossifov et al. 2014; Iossifov et al. 2012; Neale et al. 2012; O’Roak et al. 2012; Pinto et al. 2014; Sanders et al. 2012), and confirmed the critical role of de novo germline mutation in the phenotypic presentation of ASD (Sanders et al. 2015).

Until recently, studies that attempted to investigate the role of common variation in ASD often proved insufficiently powered to reliably identify statistically significant findings. A population-based study resolved such limitations by analyzing the complex interplay of common, rare, inherited, and de novo variation across a Swedish epidemiological sample (Gaugler et al. 2014). The study concluded that while high-impact rare variation,

especially *de novo* mutations, may largely determine the individual liability for developing ASD, common variants account for the most substantial contribution to the narrow-sense heritability.

In the investigation of *de novo* variation implicated in ASD, the most common study design involves the study of simplex families, either classified as trios (affected proband and two unaffected parents) or quartets that also include at least one unaffected sibling. Across these studies, most estimates suggest that as many as 1000 genomic loci underlie risk for ASD. To assess the contribution of risk-conferring *de novo* mutations, researchers have assessed the recurrence of disruptive genetic events within the same gene or genomic loci as well as the significance of such recurrence, while burden analyses evaluated the presence or absence of significant enrichment among classes of mutations in cases compared to controls.

Across multiple studies of genetic variation in ASD, burden analyses consistently demonstrate a significant excess of *de novo* loss-of-function (LoF) or likely-gene-disrupting (LGD) mutations in probands that result in a premature truncation of the gene, shift in the protein reading frame, or canonical splice site variant across large cohorts (De Rubeis et al. 2014; Iossifov et al. 2012; O’Roak et al. 2011; Sanders et al. 2015). While statistical evidence for the contribution of *de novo* missense mutations in ASD appears less robustly replicated in the literature, some studies have demonstrated the importance of such variation in the development of ASD (Sanders et al. 2012), especially those missense variants predicted to be damaging by tools such as PolyPhen-2 (De Rubeis et al. 2014).

Multiple studies have confirmed the importance of rare CNVs as a source of risk in the genomic architecture of ASD (Bucan et al. 2009; Kumar et al. 2008; Marshall et al. 2008; Mefford et al. 2008; Moreno-De-Luca et al. 2013; Pinto et al. 2010, 2014; Sanders et al. 2011; Sanders et al. 2015; Sebat et al. 2007; Weiss et al. 2008). Indeed, two studies have further shown that *de novo* CNVs in individuals diagnosed with ASD demonstrated greater frequency, length, and intersection of disrupted genes when compared to

controls (Pinto et al. 2014; Sanders et al. 2015). Beyond such findings, one study hypothesized that separate classes of mutations may converge on a common set of genes associated with ASD.

Function

Bolstered by the development of advanced statistical modeling methods and software packages, researchers have sought to translate genetic findings of *de novo* variation associated with ASD into a broad understanding of the pathophysiological mechanisms that underlie ASD neurobiology. The central methodology of such translational efforts remains guided by two central principles: (1) recurrent *de novo* LGD or damaging missense mutations that occur within the same gene in unrelated individuals point toward genes that are likely to be associated with ASD, given the infrequency of such occurrences; and (2) risk loci and risk genes that share the same associated phenotype will converge in functional clusters that correlate to shared biological pathways, regulatory functions, developmental context, or coexpression networks.

Several seminal papers that investigated genetic regulatory networks implicated in ASD with a statistically robust framework led to a finding widely replicated throughout the literature: a convergence on genes that encode for critical components of networks involved in proper synaptic function, chromatin modification, and the regulation of transcription in ASD (De Rubeis et al. 2014; Pinto et al. 2014; Sanders et al. 2015). Among these genes, both *de novo* CNVs and *de novo* LGD mutations have been shown to play a role in establishing such convergence, further emphasizing the possibility that different classes of variation may target a common biological set of ASD risk genes.

These pathways, however, include a diverse variety of biological components, from voltage-gated ion channels to histone-modifying enzymes. Specifically, one report identified significant enrichment for histone-modifier genes, which encode histone-modifying enzymes (De Rubeis et al. 2014). These histone-modifying enzymes work in tandem with chromatin remodelers to

read and recognize posttranslational modifications and ultimately activate or repress transcription. Another report further hypothesized that genes involved in chromatin modification may in fact regulate the expression of synaptic genes (Sanders et al. 2015). Such a theory draws support from findings that show both direct and indirect regulatory targets of CHD8 are strongly enriched for genes both associated with ASD and implicated in neuronal and developmental pathways that control synapse formation (Cotney et al. 2015; Sugathan et al. 2014).

Indeed, while clear evidence exists for the role of synaptic proteins and chromatin remodelers in the pathophysiology of ASD, a polygenic, complex disorder such as ASD likely results from disruptions in multiple distinct biological pathways. Studies of genetic regulatory networks in ASD have demonstrated the potential for future diagnostic and therapeutic targets through the convergence of ASD-risk genes in biological pathways related to neuronal development, kinase signaling cascades, as well as brain-expressed genes (Geschwind and State 2015). Rare gene-disruptive events in ASD have further been shown to occur in genes found to interact with the neuronal RNA-binding protein known as fragile X mental retardation protein, or FMRP-associated genes (Darnell et al. 2011; Iossifov et al. 2012; Pinto et al. 2014). The significant enrichment of FMRP targets among ASD risk genes further emphasizes the role of proper human adaptation, neuroplasticity, and synaptic function in protecting against the development of ASD.

In keeping with the theory that ASD-associated genes may form functional networks or clusters, convergence may exist across diverse biological functions, but in a highly specific developmental context. Indeed, a large number of genes that gave rise to the significant signal for enrichment among chromatin and transcription regulators involved genes with a prenatal expression profile (Pinto et al. 2014). Using data from the BrainSpan atlas, one study demonstrated highly significant findings for the convergence of coexpression networks harboring ASD-associated genes underlying the proper function of deep-layer glutamatergic cortical projection neurons in

two overlapping periods of midfetal human development corresponding to 10–24 post-conception weeks (Willsey et al. 2013). Such a result highlights the promise that clues about the pathophysiological mechanisms implicated in ASD may exist not just in shared biological functions but also in shared cell types or developmental timeframes.

Path of Physiology

Narrow-sense heritability estimates for ASD range from 17% to 50%, with such wide discrepancies likely derived from differences in study design, cohort composition (e.g., simplex vs. multiplex families), sample size, and ascertainment bias. Though as previously discussed, a population-based study suggested that narrow-sense heritability is roughly 52% for ASD, with most of the total heritability explained by common variation and only a small fraction attributable to rare de novo mutations (Gaugler et al. 2014; Klei et al. 2012).

However, though these de novo events contribute modestly to the variance in liability for ASD, de novo carrier status determined affected status for ASD in 80% of de novo CNV carriers and 57% of de novo LGD carriers (Gaugler et al. 2014). A separate study of the genomic risk loci underlying ASD found that roughly 70% of de novo CNVs and 46% of de novo LGD mutations carried ASD risk, with both estimates higher among females than males (Sanders et al. 2015). Of individuals affected with ASD, multiple studies estimate the contribution of de novo CNVs and/or de novo SNVs in mediating ASD risk at roughly 10% (Iossifov et al. 2012; Sanders et al. 2015).

Phenotypically, deviations in head circumference in either direction, a history of seizures, and the presence of an unaffected sibling in the family all increased the mutational burden of a de novo event. While several studies have demonstrated a significant increase in ASD risk with increased paternal age (De Rubeis et al. 2014; Dong et al. 2014; Iossifov et al. 2012; O’Roak et al. 2012; Saha et al. 2009; Sanders et al. 2012), other studies did not observe such a difference with either a

higher paternal or maternal age (Sanders et al. 2015). Additionally, investigations of the genetic risk architecture of ASD, particularly the demonstrated convergence of genomic risk loci in regulatory networks associated with synaptic function, have shown that common genetic mechanisms may underlie frequently comorbid disorders such as intellectual disability (ID), schizophrenia, developmental delay, and epilepsy (De Rubeis et al. 2014; Sanders et al. 2015; Zoghbi and Bear 2012).

TR; American Psychiatric Association [APA] 2000). Individuals suffering from general anxiety commonly experience distress with accompanying disturbances of sleep, concentration, and social or occupational/academic functioning.

Categorization

Diagnostic criteria for GAD as defined by the DSM-IV-TR (APA 2000) are as follows:

- Excessive anxiety and worry that occur more days than not for at least 6 months, about a variety of events, circumstances, or activities (such as work or school performance).
- The worry is difficult for the person to control.
- The anxiety and worry are associated with three or more (in children, one or more) of these six symptoms (with at least some symptoms present for more days than not for the past 6 months): restlessness or feeling keyed up or on edge, being easily fatigued, difficulty concentrating or mind going blank, irritability, muscle tension, and sleep disturbance (difficulty falling or staying asleep, or restless unsatisfying sleep).

General Anxiety

Synonyms

GAD

Short Description or Definition

General anxiety, or generalized anxiety disorder (GAD), is marked by excessive anxiety and worry occurring more days than not for at least 6 months, about a number of events or activities (DSM-IV-

The diagnostic criteria for GAD apply to individuals with ASD; however, it is important to consider that symptoms may be qualitatively different with variable behavioral manifestations within the context of an ASD (cf. Wood and Gadow 2010). For example, anxiety may be more associated with acting out behaviors in children with ASD than in typically developing children (White et al. 2009). Individuals with ASD often have limited insight or ability to express emotion (e.g., Hill et al. 2004), which may lead to frustration and consequent acting out behaviors. Careful assessment is needed to determine whether observed behaviors reflect ASD, anxiety, disruptive behavior symptoms, or a combination thereof.

Epidemiology

Anxiety disorders are prevalent among youth and adults with ASD. Specific phobias, social anxiety

(social phobia), and GAD are common subtypes. Epidemiological reports of large and/or national samples indicate that anxiety disorders in typical youth range from 10% to 20% (Achenbach et al. 1998; Shaffer et al. 1996). An early study indicated that approximately 4.9% of typical adolescents met criteria for GAD at some point in their lives (Whitaker et al. 1990).

Symptoms of anxiety may be the most common associated psychiatric concern among individuals with ASD (Skokauskas and Gallagher 2010) and occur so frequently that they are sometimes assumed to be a component of the disorder. In fact, in many cases, it is difficult to distinguish between symptoms of anxiety and ASD (see below: Part H. Evaluation and Differential Diagnosis). Comorbid anxiety disorders are reported in 11–84% of youth with ASD (e.g., Sukhodolsky et al. 2007), which is more common than in typically developing youth, youth with conduct disorder, and even some otherwise typical clinically anxious youth.

Natural History, Prognostic Factors, and Outcomes

Individuals with general anxiety tend to report a slow, gradual onset of chronic worry rather than a sudden manifestation of symptoms. Children who have general anxiety have reported that greater impairment is associated with intensity of worries, number of associated symptoms (e.g., restlessness, trouble concentrating), and number of worry domains (e.g., school, family); according to clinicians, greater impairment is associated with intensity of worries, number of associated symptoms, and number of comorbid DSM-IV disorders (Layne et al. 2009). If not treated properly, anxiety disorders in youth predict adult anxiety disorders; more than half of adults with anxiety and mood disorders had a history of a childhood anxiety disorder (Ferdinand and Verhulst 1995; Kessler et al. 1994). Some youth with anxiety disorders may experience fluctuation or a remission of symptoms, but more often, childhood anxiety disorders are chronic and precede anxiety or mood disorders later in life (Keeton et al. 2009). In

terms of vulnerability factors for developing anxiety, evidence suggests that being female, having high trait anxiety, and significant life events predict presence of chronic anxiety in adulthood (de Beurs et al. 2000).

Family liability, temperament, and environmental factors may also contribute to the development of GAD. In a large community sample, GAD in adulthood was associated with parental GAD, high behavioral inhibition, exposure to childhood separation events, and parental overprotection (Beesdo et al. 2010). High emotionality and shy temperament are prominent features in teens with anxiety as well as their parents and siblings (Masi et al. 2003). As well, offspring of anxious parents have a significantly greater chance of developing an anxiety disorder (Micco et al. 2009). Common traits in parents and siblings suggest a shared genetic liability for the development of anxiety disorders. In fact, a meta-analysis of available twin studies estimated a heritability rate of 0.32 for GAD (Hettema et al. 2001).

Similarly, it has been suggested that maternal mood symptoms, such as interpersonal sensitivity, hostility, phobic anxiety, depression, and anxiety, may be related to depression and anxiety in youth with ASD (Mazefsky et al. 2010). High rates of psychopathology in first-degree relatives of individuals with ASD may suggest a common genetic liability to develop ASD and disorders such as anxiety. In fact, it has been proposed that a multigenic form of inheritance (i.e., involving multiple genes) results in a “lesser variant” of ASD in some individuals, manifesting with anxious and obsessive traits rather than the full-blown disorder (Wilcox et al. 2003). The lesser variant has also been referred to as the “broad autism phenotype,” which comprises a constellation of subtle social and communication impairments, in addition to increased rates of psychopathology, in some relatives of individuals with ASD (e.g., Bolte et al. 2007). Higher rates of depression and anxiety in nonautistic relatives of individuals with ASD do not appear to be accounted for by the stress of raising a child (or children) with autism, providing further support for common genetic substrates (Piven and Palmer 1999).

Clinical Expression and Pathophysiology

Clinical features. Individuals with GAD are characterized by excessive fears and worries about a range of issues, such as natural disasters, illness, or the future. Common domains of worry among children include school performance, the health of significant others, minor daily events (e.g., saying the wrong thing), social status, family concerns, and natural phenomena (Layne et al. 2009; Masi et al. 2004). In addition to persistent worry, youth with GAD experience other difficulties including restlessness and trouble relaxing, trouble concentrating and attending, and trouble sleeping (Layne et al. 2009). It is common for youth to seek excessive reassurance, respond negatively to routine criticism and evaluation, have a negative self-image, experience irritability, and have physical complaints (DSM-IV-TR; Masi et al. 2004). Such difficulties can cause significant distress and may interfere with school performance, the development and maintenance of peer relationships, and family functioning (e.g., by leading to conflict).

Relation to gender. In a large prospective community cohort of youth followed from late childhood to late adolescence, girls were more likely to have all types of anxiety than boys (Van Oort et al. 2009). This is consistent with previous findings indicating that GAD is more commonly reported in girls, and the gender difference is present by late childhood. Despite the gender disparity, boys and girls with GAD appear to have similar numbers and types of symptoms (Masi et al. 2004).

Relation to age. Due to the gradual onset of chronic worry, it can sometimes be difficult to determine the exact age when symptoms develop. However, available evidence suggests GAD has an average age of onset of 8.5 years (Masi et al. 2004) and symptoms may increase in middle adolescence (Van Oort et al. 2009). It can be diagnosed as early as symptoms of worry can be verbalized by children or inferred with confidence by parents.

Though core ASD symptoms may improve as youth with ASD enter adolescence (Seltzer et al. 2004), some individuals with ASD experience greater risk for the development of psychopathology at this time. Compared to their typically

developing peers, increased rates of psychopathology, including anxiety and depression, have been reported by adolescents with ASD, as well as their teachers and parents (Hurtig et al. 2009). It may be that increased awareness of their own challenges and the complex social milieu of adolescence exacerbate anxiety in ASD (White et al. 2009).

Relation to cognitive functioning and verbal ability. Although anxiety symptoms are present among individuals with ASD who have a range of cognitive functioning, the type of anxiety may vary depending on cognitive and verbal ability. For example, in higher functioning youth, anxieties can be better articulated and may consist of persistent worrying about performance or that something bad might happen; in youth with less verbal capacity, anxiety may manifest more behaviorally, such as reluctance to change a routine in order to avoid a novel situation. Evidence does suggest that anxiety is more common in higher functioning youth, such as those with Asperger syndrome (e.g., Gadow et al. 2005); however, such findings may reflect better ability to verbally report and express psychiatric symptoms.

Relation to other problems. Pediatric anxiety disorders in typically developing youth predict other childhood sequelae such as substance abuse problems, suicide attempts, and hospitalization (e.g., Kendall et al. 2004). Anxiety disorders have also been associated with significant functional impairment, behavioral problems, and heightened symptomatology in youth with ASD. For example, higher parent-rated anxiety in youth with ASD was associated with greater impairment in social responsiveness (Sukhodolsky et al. 2007) and social skills deficits (Bellini 2004). Several large studies of children with ASD have found strong linkages between high anxiety and increased severity of ASD symptoms such as repetitive behaviors (e.g., Sukhodolsky et al. 2007), sensory symptoms (Ben-Sasson et al. 2008), and total ASD symptoms even when controlling for intellectual impairment, social maladjustment, and degree of speech impairment in a causal model (Kelly et al. 2008). Heightened fears and anxieties in youth with ASD have also been

associated with more externalizing behavioral problems, including conduct, impulsivity, and hyperactivity (Evans et al. 2005). In another study of the pediatric ASD population, high levels of parent-rated anxiety were strongly associated with more loose associations in a performance-based assessment of formal thought disorder (Solomon et al. 2008).

Pathophysiology. In terms of neuropathology, research indicates that the amygdala plays a primary function in the development and expression of anxiety, given its role in processing emotional cues (e.g., Phelps and LeDoux 2005), particularly fearful stimuli. Youth with general anxiety tend to exhibit increased activation in neural fear circuitry, including the amygdala, in response to fearful stimuli (e.g., McClure et al. 2007). Interestingly, abnormalities of the amygdala have also been implicated in the development and maintenance of social impairments (e.g., Baron-Cohen et al. 2000) and abnormal fears and high rates of anxiety in ASD (Amaral and Corbett 2003). In terms of neurobiological vulnerability, the serotonin transporter gene has been implicated in a number of anxiety disorders as well as in ASD.

Evaluation and Differential Diagnosis

Evaluation. As summarized by Keeton et al. (2009), three primary aspects of anxiety are evaluated during diagnostic assessment: anxious behaviors, thoughts, and physical symptoms (Keeton et al. 2009). In terms of behavior, clinicians observe and probe for avoidant behavior and its functional impact on daily activities. It is also important to identify thought patterns related to the child's anxiety. Youth with general anxiety may report more worries, ask more questions (e.g., reassurance seeking), and have more thoughts reflecting concerns about performance. Older children and adolescence may be able to articulate their thoughts and worries, whereas age-appropriate approaches (e.g., use of cartoons/pictures, thought bubbles) may be required to facilitate description of thoughts and feelings in younger children. Physical symptoms, including headaches, gastrointestinal problems, dizziness,

and restlessness, are common among youth with anxiety disorders. It can be helpful for a physician to rule out medical problems before assessing for an anxiety disorder. During the assessment for anxiety, clinicians should review ways in which physical symptoms may interfere with daily functioning, such as sleep, appetite, and school performance. A thorough clinical evaluation would include assessment of other psychiatric concerns as well as family mental health history, and discussion (and perhaps observation) of the child's functioning in different contexts (e.g., school, social, and home).

Anxiety is commonly assessed through clinical interview and rating scales from parents/caregivers, children, and teachers, following a multi-informant, multimethod approach. Semi-structured diagnostic interviews, such as the Kiddie Schedule for Affective Disorders and Schizophrenia (KSADS; Ambrosini 2000) and the Anxiety Disorder Interview Schedule (ADIS; Silverman and Albano 1996), have parent and child versions to allow for consensus scoring. Rating scales, such as the Multidimensional Anxiety Scale for Children (MASC), Screen for Child Anxiety Related Emotional Disorders (SCARED), the Revised Child Anxiety and Depression Scale (RCADS), and the Pediatric Anxiety Rating Scale (PARS), also have parent and child versions and correspond to DSM-IV criteria for anxiety disorders.

Because few measures to assess anxiety have been developed and validated for use with individuals with ASD (one exception: the parent-report Childhood Anxiety Sensitivity Index; CASI), clinicians and researchers tend to utilize the same measures as those used in the typical population. Despite the utility of these measures in documenting the presence of anxiety in youth with ASD, it is important to note that symptoms of anxiety may manifest differently in youth with ASD; moreover, dependence on child and parent report to evaluate anxiety can be problematic in ASD. Individuals with ASD are often characterized by diminished ability to think abstractly or communicate effectively through speech or facial expression and often lack awareness of internal states or motivation to report symptoms (Lainhart

and Folstein 1994). Research has shown that children with ASD provide less coherent representations of emotional experiences than their typical peers (Losh and Capps 2006). Children may not verbally express their feelings and worries to parents, and internalizing symptoms are not always easily observed by caretakers (Kuusikko et al. 2008). When evaluating possible anxiety symptoms in youth with ASD, it is important that a skilled clinician, familiar with both ASD and general anxiety, interpret child report, parent report, and observed behaviors with these considerations in mind.

Using a modified version of the Kiddie Schedule for Affective Disorders and Schizophrenia (Geller et al. 1996), Leyfer and colleagues developed and piloted the Autism Comorbidity Interview-Present and Lifetime Version (ACI-PL) (Leyfer et al. 2006). Based on the ACI-PL, 44% of children in the study had specific phobia, which is much higher than rates found in typically developing children and adolescents. Interestingly, generalized anxiety disorder occurred at low rates in the ASD group (2%; Leyfer et al. 2006). Higher rates of anxiety disorders have been reported in other studies (e.g., 84% using the Diagnostic Interview Schedule for Children; Muris et al. 1998), suggesting that different assessment approaches may yield variable rates.

Differential diagnosis. General anxiety rarely occurs in isolation; in a sample of 157 children and adolescents, another psychological disorder was present in 93% of the patients (Masi et al. 2004). GAD can have a similar clinical presentation as other anxiety disorders, including panic disorder, social phobia, separation anxiety disorder (SAD), and obsessive-compulsive disorder (OCD). Some symptoms also overlap with depression (as well as the basic pattern of ruminative thought), and the two disorders are highly comorbid in many samples. Symptoms of anxiety can also appear similar to symptoms and behaviors associated with autism spectrum disorders (e.g., perseverative thought and speech).

Other anxiety disorders: In both typical and ASD populations, it is important to consider how symptoms of general anxiety might overlap with other anxiety disorders. Masi et al. (2004)

reported that comorbid anxiety disorders were present in 75% of the youth in their sample of youth with GAD (Masi et al. 2004). It can be difficult to make the distinction between panic disorder and GAD, especially when individuals with general anxiety experience acute situational or anticipatory anxiety (i.e., heightened anxiety in certain situations); this can be particularly challenging in youth with ASD, who reportedly have more fears related to “specific situations” (Evans et al. 2005). One distinguishing factor is that panic attacks do not generally occur with preceding generalized anxiety (Rickels and Rynn 2001). General anxiety commonly overlaps with *social phobia* as well. Individuals with social phobia exhibit phobic avoidant behavior that is specific to a social situation, whereas someone diagnosed with GAD may have “free-floating” anxiety (i.e., not restricted to particular circumstances) that contributes to feelings of apprehension, causing a person to be shy or uncomfortable in public (Rickels and Rynn 2001). Among youth with GAD, SAD has a high rate of overlap (e.g., 31.8%; Masi et al. 2004) and tends to precede the onset of GAD. Youth who have both SAD and GAD tend to be younger, report more physical symptoms, and have a higher incidence of panic disorder than youth with GAD alone. It can also be difficult to discriminate between OCD and general anxiety, and the two disorders frequently co-occur (see Comer et al. 2004 for review). OCD is characterized by excessive recurrent thoughts (i.e., obsessions) and sometimes accompanied by repetitive and purposeful behavioral attempts to reduce the anxiety (i.e., compulsions; DSM-IV-TR). Such symptoms can be easily confused with GAD when it is unclear whether a child’s recurrent thoughts reflect true, irrational obsessions or more general worrying.

Depression: Anxiety and depression are highly comorbid, and depressive disorders may occur in over half of typical youth with GAD (Masi et al. 2004). The presence of depressive symptoms may cause increased interference with daily activities and more functional impairment and predict worse outcome in individuals with GAD. Evidence also suggests that anxiety disorders may precede and be a risk factor for the

development of depression later in life (Beesdo et al. 2010).

ASD: Symptoms of anxiety and ASD may have similar overt manifestations in some cases, making it difficult to interpret behaviors and determine whether they reflect symptoms of anxiety or ASD. For example, avoidance of unfamiliar situations is a commonly observed feature of ASD and general anxiety even though underlying symptom composition and motivating factors may differ (e.g., lack of interest vs. anxious apprehension). As a second example, many individuals with ASD are sensitive to sensory stimuli such as loud noises; similarly, individuals with general anxiety may have a heightened “startle response” or reaction to sudden loud sounds. Third, persistent, repetitive thought (and associated speech) characterizes both ASD and GAD for many individuals: in the former case, often taking the form of perseverative “special” interests, and in the latter case, worry and catastrophizing. Although the affective content often differs, the inability to shift attention away from specific thoughts is common to both ASD and GAD (Wood and Gadow 2010). It is important to consider the possibility that anxiety symptoms are present and are not accounted for by symptoms expected to occur as part of an ASD. “Diagnostic overshadowing” of psychiatric problems by developmental disabilities (Davis et al. 2008; Reiss 1982) may tend to obscure anxiety disorders in youth with ASD such that clinicians may conceptualize anxiety symptoms as falling under the umbrella of ASD criteria when in fact they represent a coexisting anxiety disorder. In recent years, mounting evidence has suggested that many individuals with ASD do have a coexisting anxiety disorder (e.g., Leyfer et al. 2006); however, more work needs to be done to develop accurate ways of assessing for anxiety in this population.

Treatment

Treatment for general anxiety in children should ideally involve parents as well as the child. Depending on the individual characteristics of the child and the treatments available to families,

children with general anxiety may benefit from behavioral intervention, medication, or a combination of both.

Behavioral treatments (CBT). There is an abundance of evidence indicating that cognitive-behavioral therapy (CBT) is effective (e.g., Walkup et al. 2008); it is considered the treatment of choice for pediatric anxiety. Numerous randomized controlled trials conducted with children have demonstrated that CBT is efficacious and significantly decreases remission rates (e.g., Cartwright-Hatton et al. 2004). Manualized CBT programs, such as the Coping Cat program (Kendall 2000), have been used extensively with anxious youth. The CBT approach assumes that pathological anxiety reflects the interaction between cognitive distortions, somatic or physiological arousal, and avoidance of fearful stimuli. As such, therapists help children identify beliefs and thought patterns that may be irrational and unrealistic and replace them with rational or realistic perspectives (i.e., cognitive restructuring). Other components of CBT usually include psychoeducation with children and parents, problem solving, relaxation training and techniques to manage physiological arousal, modeling, and imaginary or in vivo exposure to increasingly anxiety-provoking stimuli. Intervention should also include strategies to maintain treatment gains and prevent relapse.

Cognitive-behavioral therapy must be tailored to the developmental level of the child, including cognitive capacity (Sauter et al. 2009). This is especially relevant when treating symptoms of anxiety in youth with ASD. Recent evidence suggests modified CBT can effectively target symptoms of anxiety in children with ASD, particularly when a parent component is included (Chalfant et al. 2007; Reaven 2009; White et al. 2009; Wood et al. 2009). For example, Wood’s manualized CBT intervention for youth with comorbid ASD and anxiety (Wood et al. 2009) incorporates parents into each of the weekly treatment sessions; parents then implement strategies at home to facilitate generalization. Symptoms of anxiety are addressed using core components of CBT, such as hierarchical exposure therapy techniques. However, to address developmental level, social

challenges, and other unique characteristics associated with having an ASD, modifications are made to the intervention. For instance, therapeutic concepts are taught using multimodal stimuli (e.g., discussion scaffolded by drawing or writing), and concrete examples are provided rather than abstract descriptions of symptoms and cognitive processes. Children's special interests may be used as metaphors to maintain enthusiasm and motivation. In Wood's manualized intervention, youth and parents are also taught friendship skills, which are practiced at school, in the community (e.g., playgrounds), and on playdates and sleepovers. In addition to the amelioration of anxiety symptoms, improvement in parent-reported core autism symptoms has been reported in children receiving CBT for anxiety compared to children in a waitlist group (Wood et al. 2009). This suggests identification and appropriate treatment of associated symptoms of anxiety can impact core symptoms of autism, thereby improving global functioning.

Pharmacological treatments. Selective serotonin reuptake inhibitors (SSRIs) have been established as the most effective pharmacological approach for children with general anxiety. For example, in a randomized, double-blind comparison of an SSRI (fluvoxamine) and placebo in youth between the ages of 6–17, the SSRI was significantly more effective in reducing anxiety symptoms (Walkup et al. 2001). Nevertheless, there is limited information on the long-term safety of medication use in youth with anxiety, and this remains a continued focus of research. Available evidence does point toward the efficacy of both CBT and treatment with SSRI, with recent findings suggesting that combination of the two approaches provides maximum benefit (Walkup et al. 2008).

Although pharmacological treatments have not demonstrated consistent efficacy in treating core symptoms of ASD, it is possible that medications, including SSRIs, can ameliorate associated psychiatric symptoms (e.g., Kolevzon et al. 2006). The appropriate use of medications that help regulate emotion in ASD might theoretically facilitate a child's capacity to benefit from educational

and behavioral modification interventions. However, clinical trials need to be conducted to determine whether pharmacological approaches effectively target anxiety in this population.

Definition

General case programming is an instructional process with the ultimate goal of increasing the likelihood that a learner will generalize a skill set (i.e., target behavior) learned during structured teaching situations to relevant real-world settings and situations in which the target behavior should be demonstrated.

General case programming can be broken into three phases: design, implementation, and assessment. The design phase is key to general case programming and begins with analysis of the target skill to be taught. The instructor must identify the essential behaviors and all variations of those behaviors that are necessary for successful performance of that skill in relevant situations. The instructor must also consider and identify the full range of stimuli that may be encountered when the

learner engages in the target skill in real-world settings. After analysis of the relevant behaviors and stimuli, the instructor can select teaching materials that encompass as many of the behavioral and stimulus variations as possible. To reduce the likelihood of overgeneralization (engaging in the target behavior in inappropriate situations), the instructor must also identify materials that share some, but not all, characteristics with the target skill materials and ensure the learner does not engage in the target skill inappropriately. During the implementation phase, the instructor exposes the learner to the selected materials and teaches the relevant behaviors using teaching strategies appropriate for the learner (see Horner et al. 1982, 1986; Horner and Albin 1988 for recommendations on presentation order of examples). Implementation continues until the learner demonstrates success with at least one set of materials. In the assessment phase, the learner is exposed to untaught examples to test for generalization. If necessary, additional sets of materials can be used during subsequent teaching sessions until the learner shows generalization or is taught the full variety of relevant responses including the full variety of materials.

In sum, general case programming is an instructional process that is designed to increase the efficiency of teaching and subsequent likelihood of generalization of new skills. General case programming is based on thorough analysis of target skills sets and selection of materials that include the full variations in behaviors and materials likely to be encountered in real-world situations.

Definition

The term generalization, defined most broadly (Stokes and Baer 1977), is used to describe

when skills learned in a training environment transfer to the natural environment after training has ended. Generalization, in its more narrow definition, is a behavioral term that is used to describe the spread of effect of a training procedure to untrained stimuli and responses, as well as the durability of treatment effects over time. Generalization includes three specific forms: Stimulus generalization, response generalization, and maintenance. Stimulus generalization involves the occurrence of a behavior in response to another similar stimulus. For example, a child who learns to say “ball” (behavior) in response to a picture of a ball (trained stimulus) shows stimulus generalization if he says “ball” in response to an actual ball (new stimulus). Response generalization involves the spread of an effect of a trained response to other similar responses. For example, a child who is taught to greet another person by saying “Hi,” also begins to greet people by waving. Maintenance involves the continued use of a trained behavior over time, after the direct intervention period has ended.

An important outcome of any intervention is that its effects generalize to similar stimuli outside of the treatment setting. Without generalization, the ability to use a given skill may be confined to a highly specific environment or stimulus, and thus is not particularly valuable for use in real-world contexts. For individuals with ASD, generalizing skills to new settings, new people, or in response to new events can be especially challenging. In addition, it is important that the effects of intervention lead to generalized responding, such that training in one behavior leads to the development of a variety of related behaviors without direct training; otherwise, training is inefficient and leads to an inflexible pattern of behavioral responses. Further, it is critical that gains made in treatment be maintained over time, after the intervention is complete. Individuals with ASD may show deficits in skill maintenance, in part, because the types and patterns of reinforcement in the real world are often divergent from those employed in treatment settings. As such, for individuals with ASD, newly acquired skills may extinguish rather quickly in extra-therapy contexts.

It has been suggested that without targeted intervention, generalization and maintenance of skill does not occur automatically for individuals with ASD (Koegel and Rincover 1977). Some have suggested that these difficulties may be related to an insistence of sameness, stimulus over-selectivity, and/or lack of motivation in individuals with ASD (Arnold-Saritepe et al. 2009). While the etiology of these deficits remain unclear, it is obvious that without the ability to translate knowledge to various contexts, an individual will continue to experience impairment in important areas of functioning. As such, it is critical that intervention programs incorporate specific components to help encourage behavioral change outside of the direct therapy environment.

Historical Background

Difficulty with treatment generalization and maintenance for children with autism was identified as early as 1973 by Lovaas and colleagues, who noted that children in their study of intensive behavioral intervention who returned to an institutional setting lost the majority of their treatment gains; however, children who returned to live with their parents who had been trained to carry out the intervention at home continued to make gains.

Historically, generalization was conceptualized as a passive process that was a natural consequence of the inability to effectively utilize stimulus discrimination. It was thought that if generalization did not occur, an individual had been successfully taught to discriminate among specific stimuli and responses. Stokes and Baer (1977) were some of the first to argue that generalization is an active process and that it should be directly targeted as a teaching outcome. In this way, “generalization may be claimed when no extratraining manipulations are needed for extratraining changes; or may be claimed when some extra manipulations are necessary, but their cost or extent is clearly less than that of the direct intervention” (Stokes and Baer 1977). In sum, an intervention can be considered effective when relevant targeted behaviors are observed in untrained environments (e.g., across

subjects, settings, people, behaviors, and/or time) without the same schedule of prompting and reinforcement utilized in training conditions (Stokes and Baer 1977).

Building off this idea of generalization as an active process, Stokes and Baer (1977) suggested that treatments should directly target generalization and maintenance by incorporating “generalization-promotion” techniques into intervention protocols. In an initial review of the generalization literature, these authors described several “generalization-promotion” techniques that were being utilized to track and target generalization. These techniques were categorized into nine groups:

1. **Train and Hope:** These procedures document the presence or absence of generalization but do not explicitly target the generalization process.
2. **Sequential Modification:** Such procedures involve the implementation of intervention techniques and the probing for generalization. If generalization is not observed, the procedures are systematically altered to determine and then use the techniques that are most effective for promoting generalization.
3. **Introduce to Natural Maintaining Contingencies:** This process relies on incorporating into the treatment program, circumstances and reinforcement that are natural to the behaviors being taught. In this way, the reinforcement and consequences that are used in treatment are the same, or very similar to, those which are available in real-world contexts.
4. **Train Sufficient Exemplars:** These procedures involve teaching with several different examples of the same lesson until an individual is able to generalize sufficiently across related conditions and responses.
5. **Train Loosely:** This process relies on incorporating variety into the teaching conditions, settings, stimuli, and responses in order to mirror real-world situations.
6. **Use Indiscriminable Contingencies:** This process depends on the use of intermittent reinforcement, such that situations in which reinforcement would be expected are

undistinguishable from those in which reinforcement would not be expected. In this way, target behaviors should eventually occur across contexts, regardless of whether or not reinforcement is available.

7. **Program Common Stimuli:** Such procedures involve making the treatment context similar to the generalization context. Thus, the settings and stimuli utilized in training are the same or similar to those available to an individual in real-world contexts.
8. **Mediate Generalization:** This process relies on the incorporation of a particular stimulus (e.g., an object or a person) that is present in the training conditions and generalization conditions. In this way, access to the mediating stimulus during generalization will prompt the individual to use the behaviors learned in the training condition.
9. **Train to Generalize:** These procedures involve giving an individual direct instruction to generalize, or reinforcing generalization as if it were a specific behavior.

Current Knowledge

Although considerable individual variation exists with regards to the development of generalization and maintenance of skill, there is a significant body of research to indicate that certain factors can be particularly beneficial in supporting these processes. Many of these factors are based on the incorporation of the techniques described by Stokes and Baer (1977) into intervention programs. Currently, the literature indicates that implementing intervention in natural settings, using parents as intervention providers, utilizing peer-mediated intervention, and self-management are especially effective in supporting the development of skill generalization and maintenance.

Naturalistic Interventions: Some of the first effective intervention programs developed for individuals with ASD utilized a traditional behavioral approach, discrete trial training, which relies on a highly structured and controlled learning environment. In such programs,

the therapist and child usually sit face-to-face at a table with the therapist prompting the child for a series of discrete skills presented in successive trials. Child behavior is typically reinforced with food or access to a preferred toy. Discrete trial training has been shown to be effective for teaching a range of skills (e.g., Lovaas et al. 1973). However, results of these studies suggested limited generalization of skill, especially in non-treating settings, with nontreatment therapists, and in the spontaneous use of the new skill. In fact, subsequent research has demonstrated that highly structured intervention environments and artificial reinforcers can limit the generalization and maintenance of newly acquired skill (Lovaas et al. 1973; Spradlin and Siegel 1982). As such, programs utilizing behavioral techniques directly in natural contexts have emerged in order to actively promote generalization during intervention. Naturalistic behavioral interventions use prompting and reinforcement but are implemented in natural settings (e.g., during play interactions or other daily routines) and utilize more natural reinforcement (e.g., praise or the natural consequence of behavior). Examples of such programs include pivotal response training (PRT), incidental teaching, and milieu teaching. A significant amount of research has demonstrated that naturalistic behavioral techniques are effective at increasing verbal and nonverbal communication, play, imitation, and joint attention (Schreibman et al. 2015). Importantly, research has also demonstrated that the use of these types of intervention techniques promote generalization of skill to untrained stimuli, settings, and interaction partners (e.g., Kaiser and Hester 1994). Several studies have compared naturalistic and traditional behavioral approaches for teaching specific language skills (e.g., preposition use, color adjectives) as well as broader language functioning. Across studies, naturalistic behavioral approaches have been found to be superior to traditional behavioral approaches in terms of producing skill generalization (Delprato 2001; Mohammadzahari et al. 2014). As such, the literature indicates that the implementation of intervention in natural settings with natural reinforcement seems to be an

especially effective way to increase the generalization and maintenance of skill for individuals with ASD.

Parents as Intervention Providers: A variation of implementing intervention in natural contexts is to train parents as intervention providers. By training parents in intervention techniques, children are provided with increased access to intervention in more of their natural settings with their natural interaction partners. A growing body of literature suggests that parents can be successfully trained in a variety of intervention approaches to improve the quality of parent-child interactions, to produce gains in language skills, imitation skills, joint attention/joint engagement, and appropriate play skills, and to decrease problem behavior in children with ASD (e.g., Bearss et al. 2015; Green et al. 2010; Kasari et al. 2010; Wetherby et al. 2014). Moreover, generalization and maintenance of skill was observed in the majority of these studies; the children were able to utilize variations of newly acquired skill in untrained environments, with untrained interaction partners, and in response to untrained stimuli. These results indicate that using parents as agents of change can lead to better generalization and maintenance of skill for individuals with ASD.

Peer-Mediated Intervention: Another way to promote generalization and maintenance in individuals with ASD is to utilize peers in intervention programs. In this way, individuals with ASD can receive training in the classroom, the playground, and during daily routine interactions with same-age individuals. A number of studies have shown that typically developing children can be successfully trained to directly implement, or support the implementation of, naturalistic intervention techniques to elicit changes in behavior from peers with ASD (e.g., Kasari et al. 2012; Kamps et al. 2015). Research has demonstrated that the utilization of multiple peer trainers can help promote generalization of skill, particularly social-communication skills, to untrained peers (Pierce and Schreibman 1997). Moreover, additional research has suggested that peer-mediated naturalistic interventions can enhance generalization of skill to untrained environments, untrained

stimuli, and untrained interaction partners, including siblings (e.g., Belchic and Harris 1994; Chang and Locke 2016).

Self-Management: Self-management, in which the individual is taught to monitor his own behavior and to provide self-reinforcement, has also been found to be successful for producing and maintaining improvements in appropriate social interaction and play skills in individuals with autism (Carr et al. 2014). With self-management, the individual's behavior becomes under their own control, and thus the presence of a treatment provider is not necessary. This helps individuals generalize skills to new environments and maintain behavioral improvements over time in the absence of treatment providers.

In order to utilize the techniques described above in an effective and ecologically valid way, one must first consider the individual receiving instruction. Different stimuli, responses, settings, and consequences are going to be relevant and reinforcing for a given individual. In order to implement intervention to promote generalization and maintenance of skill, a thorough understanding of the individual and his or her needs is imperative.

Future Directions

Although it has been identified that individuals with ASD experience difficulties with generalization and maintenance and that some teaching techniques are more effective than others for promoting these processes, the research on the application of these techniques continues to be limited. In a 2009 review of the intervention literature, Arnold-Saritepe and colleagues found that more than 40% of entries did not evaluate or discuss generalization and maintenance. Thus, as a field, our understanding of the most effective ways to encourage generalization and maintenance is still somewhat restricted. It is important for researchers and clinicians to continue to utilize, explore, and expand upon the techniques described above in order to actively target generalization and maintenance of skills in individuals with ASD.

Generalized Anxiety Disorder

Ana Figueroa Quintana
Child and Adolescent Psychiatry Unit, Hospital
Perpetuo Socorro, Las Palmas, Spain

Synonyms

GAD

Short Description or Definition

Generalized Anxiety Disorder does not go under any other denomination.

The DSM-IV-TR includes Overanxious Disorder of Childhood (DSM-III-R) in this category.

Generalized Anxiety Disorder (GAD) is characterized by the presence of *excessive and uncontrollable worries* about a number of life events such as weather, illnesses, natural disasters, risky situations, failure, or the future. These worries are accompanied by at least three of the six possible associated symptoms of negative affect/tension: restlessness, feeling keyed up, or on edge; easily fatigued; difficulty concentrating, mind going blank; irritability; muscle tension; and sleep disturbance. Because usually one or more situations provoke these symptoms, the patient tends to avoid them. *Avoidance behavior* is a cardinal symptom of all anxiety disorders, including GAD (Table 1).

Generalized Anxiety Disorder, Table 1 Diagnostic criteria for DSM-IV generalized anxiety disorder

(A) Excessive anxiety and worry (apprehensive expectation), occurring more days than not, for at least 6 months, about a <i>number of events</i> or activities (such as work or school performance)
(B) The person finds it <i>difficult to control</i> the worry
(C) The anxiety and worry are associated with <i>three (or more)</i> of the following six symptoms (with at least some symptoms present for more days than not, for the past 6 months). Note: <i>Only one item is required in children</i>
(1) Restlessness, or feeling keyed up or on edge
(2) Being easily fatigued
(3) Difficulty concentrating or mind going blank
(4) Irritability
(5) Muscle tension
(6) Sleep disturbance (difficulty falling or staying asleep, or restless unsatisfying sleep)
(D) The <i>focus</i> of the anxiety and worry is <i>not confined to features of an Axis I disorder</i> , for example, the anxiety or worry is <i>not</i> about: having a panic attack (as in panic disorder), being embarrassed in public (as in social phobia), being contaminated (as in obsessive-compulsive disorder), being away from home or close relatives (as in separation anxiety disorder), gaining weight (as in anorexia nervosa), having multiple physical complaints (as in somatization disorder), or having a serious illness (as in hypochondriasis), and the anxiety and worry do not occur exclusively during posttraumatic stress disorder
(E) The anxiety, worry, or physical symptoms cause <i>clinically significant distress or impairment</i> in social, occupational, or other important areas of functioning
(F) The disturbance is <i>not due</i> to the direct physiological effects of a <i>substance</i> (e.g., a drug of abuse, a medication) or a <i>general medical condition</i> (e.g., hyperthyroidism), and does not occur exclusively during a mood disorder, psychotic disorder, or a pervasive developmental disorder

Due to their *multiple and uncontrollable worries*, the patient has a constant level of arousal and a sense of impending doom but does not develop panic attacks. Patients with GAD frequently emphasize the negative aspects, have unrealistic expectancies about the future, ask too many questions, feel insecure about their competencies, seek constant reassurance, and respond negatively to ordinary criticism and evaluation (Keeton et al. 2009).

Physical symptoms (or somatic complaints) are common in patients with GAD: nausea, abdominal pain, dizziness, headache, tachycardia, sweating, etc. Many patients have previously visited other medical specialties to rule out medical problems.

All these symptoms often interfere, sometimes severely, in the patient’s sleep, concentration, and eating habits; and they can alter his/her capacity for normal relationships (with peers and family). To meet diagnostic criteria, *symptoms must provoke marked distress and interfere with social, emotional, or educational functioning* (American Psychiatric Association [APA] 2000).

GAD and Autism

Currently, anxiety is not considered a phenomenological characteristic of Autism spectrum disorders (ASD; White et al. 2009). It is logical to think that the social disability associated with ASD could provoke anxiety – especially in higher functioning youth who are conscious of their deficits (White et al. 2009). In children with ASD the rate of anxiety disorders range from 18% (Gadow et al. 2004) to 87% (Muris et al. 1998). deBruin et al. (2006) found that approximately 55% of the sample of ASD had at least one anxiety disorder. Simonoff et al. (2008) reported an overall anxiety disorder diagnosis rate of almost 42%. Gjevik et al. (2011) found that 41% of the 71 children and adolescents with ASD had an anxiety disorder. These studies suggest that anxiety disorders are more frequent in patients with ASD than in the general population.

However frequent, these are rarely diagnosed with ASD due to a clinical consensus that they are better explained by the ASD itself (White et al. 2009). Given the substantial symptom overlap and the lack of clarity in differential diagnosis, this topic remains controversial.

Some of the most frequently reported anxiety disorders and symptoms seen in children with ASD are simple phobias, generalized anxiety disorder, separation anxiety disorder, obsessive-compulsive disorder (OCD), and social phobia.

There is some evidence that the prevalence of anxiety may differ across the specific diagnoses. Children with Asperger Syndrome appear most likely to experience anxiety, followed by PDD-NOS, and then Autism Disorder. These group differences must be interpreted cautiously given that diagnosis is often related to other factors such as level of cognitive functioning, which may also impact psychiatric comorbidity (White et al. 2009).

Nonetheless, identification is difficult due to the patient's concurrent difficulties with communication, the presence of other behavior problems, the lack of standardized assessments specific to these patients, and the need for greater collateral sources of assessment information (Davis et al. 2008). This explains why there is limited systematic study of the diagnosis and treatment of anxiety disorders in patients with ASD.

Categorization

GAD is not classified into categories.

Epidemiology

Lifetime prevalence of GAD in the general population ranges from 2% to 15%. GAD occurs in up to 10% of the pediatric population, most of all adolescents. Childhood-onset GAD has an average age of onset of 8.5 years. There is a 2:1 female-to-male preponderance, at all ages. Boys and girls of all ages with GAD have similar number and types of symptoms (Keeton et al. 2009).

Natural History, Prognostic Factors, and Outcomes

DSM-III was the first to include the category of GAD (APA 1980), and it did so as a residual category. The diagnosis was permitted only if

the patient did not meet criteria for another Axis I disorder. The diagnostic criteria for GAD were revised substantially in DSM-III-R (APA 1987) and then again in DSM-IV (APA 1994).

Although GAD can start in childhood or adolescence, most frequently GAD begins in early adulthood. A large proportion of patients with GAD cannot report a specific moment of onset.

Typically a person starts with subclinical symptoms, and these worsen progressively. There are no consistent differences in the clinical presentation between early onset and late onset GAD. Once it is established, GAD tends to have a chronic and persistent course. Exceptionally patients can have periods of full remission, but usually only have periods of improvement and others of worsening. Fluctuations are common, mainly related to life stressors.

If left untreated GAD may persist, and even lead to another psychiatric disorder such as another type of anxiety disorder, a depressive disorder or a substance use disorder, in adolescence or adulthood. Treatment reduces the probability of persistence and of comorbidity, thus improving prognosis. The initial severity of symptoms is a negative prognostic factor. Another prognostic factor is the parents' reaction to the child's fears. Overprotective parents usually try to diminish the child's distress by letting him avoid a stress-provoking situation, but this can, in the long term, increase the child's fear and avoidance, and prevent the development of coping skills (Keeton et al. 2009).

Impairment/Outcome

GAD is associated with significant physical and psychological symptoms and impacts health, family relationships, academic performance, and employment.

Clinical Expression and Pathophysiology

The clinical features of GAD were already reviewed.

Approximately 90% of patients with GAD have at least one other psychiatric disorder *at some point of time in their lives* (Wittchen et al. 1994).

The National Comorbidity Survey (NCS) estimated that 65% of people with current GAD had at least one other psychiatric disorder *at the time of assessment*, mainly another anxiety disorder or mood disorder (Brawman-Mintzer et al. 1993).

In children, GAD is often diagnosed with another anxiety disorder (social phobia or separation anxiety disorder), depression or ADHD. In children with GAD, co-occurrence with social phobia or separation anxiety disorder is the rule, rather than the exception. Up to 60% of *anxious children* have at least two of the three, and 30% have the three of them (Keeton et al. 2009).

Pathophysiology

The etiology of anxiety is still under study, but *biological (including genetic) and psychosocial (environmental) factors* are involved. These factors cause anxiety by modulating the following:

1. The neural circuits underlying emotion process
2. Psychological processes
3. Behavioral tendencies, including temperament

In relation to genetics, heritability of GAD is around 20–30%. Genes that increase the risk for anxiety disorders, also increase the risk for depressive disorders.

Environmental factors, such as the death of a loved one, lack of family attachment, or conflicts with peers, exert the greatest influence in the emergence of anxiety disorders. An anxiety disorder can start with external cues, but also with how the person processes them.

Moreover, genetic and environmental factors can interact to cause an anxiety disorder in a child. For example, a child can inherit an anxiety disorder from a parent. On top of that, an anxious parent may also have distinctive parenting practices, and encourage a child to maladaptive patterns of responding to ambiguous situations, such as avoiding them (Keeley and Storch 2009).

In relation to neural circuits, fear is regulated mainly by *the prefrontal cortex (PFC) and the amygdala*.

Within the PFC there are two areas involved in anxiety: The *orbitofrontal cortex* makes a representation of negative and positive reinforcers. The

anterior cingulate cortex regulates the emotional response.

The amygdala registers the emotional significance of environmental stimuli and stores emotional memories.

When circuits connecting the PFC and the amygdala are altered, the amygdala is often activated by neutral harmless stimuli. When activated, the person perceives a stimulus as dangerous; and the amygdala starts a cascade reaction, activating other brain regions, leading to the following anxiety symptoms:

- The *HPA axis*, resulting in CNS activation. The hypothalamus secretes corticotrophin releasing factor (CRF) that induces the secretion of ACTH, which induces the secretion of cortisol and adrenaline from the adrenal gland. This causes hyperglycemia and tachycardia, so that the brain and muscles respond to danger.
- The dorsomedial nucleus of the *vagus nerve* and *nucleus ambiguus*, activating the parasympathetic nervous system.
- The *parabrachial nuclei* that increases respiratory frequency, resulting in dyspnea and hyperventilation.
- The *locus ceruleus* that also releases adrenaline, which raises blood pressure and heart rate, activates sweating, and induces tremor (Revised in Soutullo and Figueroa-Quintana 2010).

Among temperamental traits, *behavioral inhibition* is the most studied.

The neurotransmitters most implicated in anxiety are serotonin and *noradrenaline*. Experts believe that anxiety appears when there is an underactivation of the serotonergic system and an overactivation of the noradrenergic system. Disruption of the gamma-aminobutyric acid (GABA) system has also been implicated. The role of corticosteroid regulation in anxiety is presently under study.

Evaluation and Differential Diagnosis

Diagnostic Evaluation

Assessment requires a multi-informant, multi-method approach involving the child, the parents,

and schoolteachers. The clinician should perform a structured or a semi-structured clinical interview. Several semi-structured diagnostic interviews are available.

For children, the *Anxiety Disorder Interview Schedule for DSM-IV (ADIS-IV)* is designed for youth aged 6–17. It assesses DSM-IV anxiety, mood, externalizing, tic, substance use, and pervasive developmental disorders.

The *Kiddie Schedule of Affective Disorders and Schizophrenia for School age children, Present and Lifetime version (K-SADS-PL)* is used for children 6–18 years old, to assess all Axis I diagnosis, except pervasive developmental disorders.

Using these interviews, the clinician should assess the three primary groups of anxiety symptoms: *behaviors, thoughts, and physical symptoms*. The clinician should explicitly ask about their presence, their frequency and how they interfere with their daily functioning. Anxious children tend to report more physical symptoms, while their parents usually emphasize the avoidant behaviors.

The evaluation should also include past psychiatric history, family psychiatric history, and medical history. If possible, it is helpful that the clinician actually sees the patient in an anxiety-provoking natural situation (i.e., school).

Rating scales completed by the patient, caregivers, and teachers should never be used as diagnostic instruments. However, they provide valuable information for the diagnosis and the monitoring of symptoms. The clinician can use several scales, none of which are specific for GAD (Keeton et al. 2009).

The Multidimensional Anxiety Scale for Children (*MASC*) is a standardized validated 39-item self-report measure for youth aged 8–19 years. It yields four factors that assemble DSM-IV anxiety diagnoses: social anxiety, separation anxiety/panic, physical symptoms, and harm avoidance. It effectively discriminates between controls and youth with anxiety and depression. However, it does not discriminate among the different types of anxiety disorders.

The *SCARED* is a 41-item measure for youth aged 9–18 years, with factors matching DSM-IV

anxiety disorders, plus school phobia, such as somatic/panic, generalized anxiety, separation anxiety, and social phobia. It effectively differentiates between anxiety and non-anxiety, anxiety and depression, and anxiety and disruptive disorders. Brief versions of the *SCARED* are available for screening and can be helpful in primary care settings. The *SCARED-R* is a revised 66-item version that includes items for separation anxiety and specific phobias, obsessive-compulsive disorder and post-traumatic stress disorder.

Other scales that can be used in children are the Spence Children's Anxiety Scale (SCAS) and the Pediatric Anxiety Rating Scale (PARS). The Hamilton Anxiety Scale can be used in adults.

Differential Diagnosis

- Normal anxiety: in a stressful situation
- Organic cause: hyperthyroidism, Cushing syndrome, etc.
- Drug use: symptoms appear only when under the effect of the drug

GAD should also be differentiated from other psychiatric disorders as follows:

- Other anxiety disorders
- Obsessive-compulsive disorder
- Depression

Treatment

There are multiple treatment options for GAD. Treatment selection depends on factors related to *the disorder* (severity, duration, dysfunction), *the patient and his/her family* (developmental age, insight, treatment preferences, family motivation and availability, and financial resources), and the clinician (availability and experience).

The *therapeutic alliance* is an essential element, and is best developed in the context of *psychoeducation*, which is also fundamental in the treatment process. Educating the family and

the child (according to his or her developmental age) increases the insight and motivation for treatment. Psychoeducation should always include the concept of anxiety as a normal emotion, etiological and maintenance factors, the natural course of the disorder, treatment alternatives, and prognosis. It is also helpful to inform them on how to manage some symptoms such as avoidance behaviors or cognitive biases.

Two treatments, cognitive-behavioral therapy (CBT) and selective serotonin reuptake inhibitors (SSRIs), have demonstrated efficacy for the treatment of pediatric anxiety disorders including GAD (Keeton et al. 2009).

CBT

Many randomized clinical trials have demonstrated short-term and long-term effectiveness of CBT. Thus, CBT has become the initial treatment of choice, except when anxiety symptoms are too severe to work with the child (medication would be indicated in this case). CBT can be given in monotherapy if symptoms are only mild. Moreover, parents often perceive CBT as a more acceptable initial treatment, compared to medication. The targets of CBT are gaining consciousness about the symptoms, controlling worries, changing the persistent over-arousal state, and confronting fears without permitting avoidance.

There are several CBT-manualized programs, which are based on classical and operant principles, and social learning. CBT is composed of psychoeducation, cognitive restructuring (like reducing negative self-talk, addressing negative thoughts), problem solving, relaxation training (addressing physical symptoms), modeling, contingency management, exposure, and relapse prevention. The duration of the treatment depends on the disorder severity and treatment response. Because of the nature of the worries that characterize GAD, patients may need greater use of imaginary than in vivo exposures.

Medications

There are a number of placebo-controlled studies assessing short-term effectiveness of different

medications in children and adolescents with GAD. There is none studying long-term effectiveness.

SSRIs

SSRIs are the first-line option. In fact, SSRIs tend to be more effective in anxiety disorders than in OCD or depression (Bridge et al. 2007). Sertraline, fluvoxamine, and fluoxetine have US FDA pediatric indications for obsessive-compulsive disorder (OCD), and fluoxetine for pediatric major depression. However, there is sufficient evidence suggesting that these and other SSRIs (such as citalopram and escitalopram) are effective for GAD and other anxiety disorders, in children and adults. There is not a universal algorithm for choosing among the different SSRI, neither in adults nor children.

The clinician should start with a low dose of an approved SSRI and titrate it weekly, assessing clinical response and side effects. Dosing can begin with 25 mg/day of fluvoxamine, 10 mg/day of fluoxetine, or 25 mg/day of sertraline, or even lower in young children. Most SSRIs can be dosed daily in the morning. Evening dosing is possible if treatment does not disrupt sleep.

However, even when a patient significantly improves by weeks 8–12, he or she frequently remains symptomatic and dysfunctional. If the patient presents only partial response, the dose should be increased. To achieve maximum benefit children may need the same dose as adults.

Clinical benefit can be observed during the first week, but it is usually in the second to fourth week that the patient refers improvement. Maximum benefit can occur over 12–16 weeks, with additional benefit accruing over 6–12 months (additive long-term effect).

This, along with the fact that anxiety disorders tend to be chronic, suggest that the treatment should be maintained for an extended period. That way, medication can help consolidate initial gains (continuing exposure to anxiety-provoking situations in an anxiety-free state); help the patient to fully benefit from CBT and work on self-concept, avoidance, social relations, etc.; and prevent relapse. In the absence of evidence, experts

recommend continuing treatment at least *1 year after achieving full remission*.

Deciding when to stop treatment may be difficult. It is not advisable to discontinue medication at the start of school, while at camp, during final exams, or even during vacations. A discontinuation trial is more appropriate when the patient can be monitored closely (to immediately assess relapse), and is in a stable environment at school and at home. As with all medications, the dose of the SSRI should be tapered progressively, avoiding abrupt discontinuation to prevent withdrawal effects. If symptoms return, medication should be restarted.

During the treatment with an SSRI, if the patient does not show clear benefit by weeks 6–8, another SSRI should be tried.

Patients usually tolerate SSRIs well. Common side effects include drowsiness, stomach aches, headaches, restlessness, and behavioral activation. These are generally mild and usually dissipate after the first weeks of treatment. If these are marked or persistent the clinician should lower the dose. If they persist, the clinician should discontinue the treatment and try another SSRI.

Sometimes, improvement could be difficult to differentiate from behavioral activation, for example, when the child becomes less fearful and starts confronting previously feared situations, and even testing the limits of adults. Apathy is a less-known, late-onset side effect; clinicians often miss it as a side effect, and classify it as a symptom, which has treatment implications. Clinicians have informed anecdotal cases of new-onset easy bleeding or bruising. In most cases, coagulation tests and bleeding times are either delayed or normal.

Rarely, a patient may suffer a manic switch or episode, characterized by changes in mood (elevated, euphoric, or irritable) or behavior (grandiosity, fast speech, higher level of energy and activity), and possible psychotic symptoms. Should it appear, this usually starts later in the course of treatment, and is less likely to remit when lowering the dose. It may diminish when discontinuing the treatment, or may require starting a mood stabilizer or an

antipsychotic. Children 10–14 years of age are considered at greatest risk for this severe side effect.

Potential risks should always be considered in the context of potential benefits. With SSRIs for the treatment of anxiety disorders, the benefits clearly outweigh the risks, but systematic tracking of side effects is mandatory. Monitoring height, weight, and physical status is also prudent. There is no need to routinely run laboratory testing or ECG at baseline or during follow-up, if the patient is asymptomatic. Also, ongoing medical symptoms should be monitored by the pediatrician or the general practitioner.

A recently published comparative treatment trial examined the effectiveness of sertraline, CBT, combination therapy with sertraline and CBT, and placebo for 488 youth aged 7–17 years, who presented GAD, Separation anxiety disorder, and/or social phobia. Response rates were based on the Clinical Global Impressions-Improvement (CGI-I) following 12 weeks of treatment. All therapies were statistically superior to placebo, and combination therapy was superior to both monotherapies. Response rates were up to 80.7% for combination therapy, 59.7% for CBT, and 54.9% for sertraline. This was the first study to examine the combined effects of CBT and SSRI for children and adolescents with anxiety disorders, and confirmed that CBT alone and sertraline alone are effective short-term treatments, and that there is a clear clinical advantage in combining both (Walkup et al. 2008).

Second-Line Medications

Venlafaxine and Duloxetine

There are some studies suggesting that noradrenaline and serotonin inhibitors, such as venlafaxine and duloxetine, may be effective in GAD and other anxiety disorders.

Tricyclic Antidepressants

Tricyclic antidepressants have demonstrated efficacy in anxiety disorders. However, they are second-line treatments because they require

pre- and post-ECG controls, have more side effects than SSRIs, and may be lethal in overdose.

Benzodiazepines

Benzodiazepines (BDZ) are frequently used in adults with GAD. Their use is more limited in children and adolescents as they have not been extensively studied in this population. Their main disadvantage is their potential for physical dependence.

Atypical Antipsychotics

Atypical antipsychotics have been studied as adjunct therapy to standard GAD pharmacotherapy in refractory patients (Bloch et al. 2006).

Other Medications

There is little evidence supporting the use of *antihistamines*, *alpha-adrenoceptor agonists*, or *melatonin*, for the treatment of anxiety disorders. However, in practice, clinicians may prescribe these if the patient presents insomnia. *Bupirone* has shown controversial results in adults, and one study could not demonstrate its effectiveness in children.

Generative Complexity

Trina D. Spencer

Rightpath Research and Innovation Center,
University of South Florida, Tampa, FL, USA
Institute for Human Development, Northern
Arizona University, Flagstaff, AZ, USA

Definition

In his 1993 book, *Origins of Order: Self-Organization and Selection in Evolution*, Stuart Kauffman proposed generative complexity as a mechanism responsible for adaptive human skills. His model suggests that organisms and their neurobiological systems will self-generate with greater complexity. Generative complexity is thought to be a result of spontaneous variation driven by genetics. This unrestrained complexity is then shaped into an organized system of adaptive variations through a Darwinian selection process. Kauffman's generative complexity extends evolutionary theories to explain how human social behavior and other complex traits have evolved. Social behaviors such as bonding, imitation, and emotional expression may be related to distinct brain circuits. Impairment in these areas may be at the level of intermediate traits (those that are between genes and social behaviors). Applying the model of generative complexity, geneticists and other researchers are working to identify intermediate traits associated with the social behavioral deficits used to diagnose children with autism.

Genetics

Paul El-Fishawy

State Laboratory, Child Study Center,
Yale University, New Haven, CT, USA

Definition

Genetics is a branch of biological science that focuses on the study of how the biological instructions for the development and functioning of living organisms are passed from generation to generation and how changes in these instructions lead to variation in the traits of organisms. In addition, genetics seeks to understand how these biological instructions operate within cells, the building blocks of living organisms.

Deoxyribonucleic acid (DNA) is the molecule that carries the instructions for the development and functioning of living organisms and that is passed down from generation to generation. The instructions are spelled out in a sequence or code of four chemical units called nucleotide bases. Certain segments of the DNA molecule called genes contain the code for creating the components of cells, most importantly, molecules called

proteins. On average, all humans possess genomes that are about 99% identical to each other. However, it is the genetic variation between individuals that is of particular interest to physicians and scientists searching for the underpinnings of human disease. It is presumed that if genetic factors increase the liability for certain conditions in a subset of the human population, the risks will be found among the small portion of the genome that varies from one person to the other.

Variations of all types, including rare mutations and common polymorphisms and sequence and structural variations, all contribute to the development of human disease. Some variations are passed from one generation to the next and give rise to inherited diseases. Mutations can also arise anew in germ cells during the creation of the zygote. These are called *de novo* mutations. Mutations can also arise in adult cell types. These are called somatic mutations.

The measure of the extent to which genetic factors contribute to a particular condition, syndrome, or disease is called heritability. Studies that compare how frequently pairs of monozygotic twins (identical twins) share a phenotype compared to how frequently pairs of dizygotic twins (nonidentical twins) share that phenotype are called twin studies. These types of studies show that autism has a high degree of heritability.

The identification of genetic factors contributing to ASD can have a number of benefits. Such knowledge can improve early diagnosis, help better predict the risk of an offspring developing autism, identify subgroups of individuals with differential responses to treatments, and contribute to a better understanding of the underlying biology of autism, which, in turn, can point to new strategies for treatment and prevention.

Genome-wide Association

Thomas Fernandez

Yale Child Study Center, Yale University School of Medicine, New Haven, CT, USA

Definition

Genome-wide association (GWA) is an approach to studying a disease or trait whereby markers (usually common genetic variants, or polymorphisms) across the genomes of many individuals with (cases) and without (controls) the phenotype are scanned in order to find genetic variations associated with the disease or trait. The associated genetic variants, with allele frequencies that differ significantly between cases and controls, can serve as powerful indicators of regions of the human genome where the phenotype-causing events reside. The effect size of a variant associated with the phenotype in a GWA study is usually reported as an *odds ratio* (ratio of proportion of individuals in the case group carrying the risk allele to proportion of control individuals carrying the same allele). Statistical significance of the odds ratio (whether it is significantly different from 1) is typically calculated using a chi-squared test. In order to protect against false positive associations that may occur with the large number of statistical comparisons required for a GWA study,

Genome-wide Association, Fig. 1 *Manhattan plot.* A scatter plot typically used to summarize results of a GWA study. Genomic coordinates are displayed along the x-axis, and the negative logarithm of association p -value

for each marker polymorphism across the genome is displayed on the y-axis. The strongest associations have the smallest p -values and therefore the largest negative logarithms

the commonly accepted genome-wide significance threshold is $p < 5 \times 10^{-8}$. GWA study results are commonly summarized by a “Manhattan plot” (Fig. 1), which shows the negative logarithm of the p -value for each marker polymorphism across the genome.

Historical Background

Prior to the introduction of GWA studies (around 2000), the main approach to investigating genetic causes of human disease was *genetic linkage* studies in families. While linkage is useful for single gene Mendelian disorders, using this approach for common and complex diseases generally yields inconsistent results. *Genetic association* arose as an alternative to linkage for detecting weaker genetic effects and was initially performed by interrogating polymorphisms in individual candidate genes between cases and controls. The *common disease-common variant* hypothesis, that common polymorphisms ($>1\%$ allele frequency) contribute to susceptibility of common diseases,

provided the rationale for the use of GWA studies to map loci contributing to common disease. In order to test this hypothesis, several tools and resources were developed and converged to allow identification of common variants throughout the genome. The completion of the *Human Genome Project* in 2003 provided a human reference genome sequence, and the *International HapMap Project* in 2005 identified a majority of the common single nucleotide polymorphisms (SNPs) investigated in GWA studies and also identified *haplotypes* which indicated those SNPs describing most of the genetic variation.

The first GWA study, published in 2005, identified two SNPs within the complement factor H gene with significantly different allele frequencies between 96 cases with age-related macular degeneration and 50 controls (Klein et al. 2005). In 2007, the Wellcome Trust Case Control Consortium reported a landmark GWA study, including 14,000 cases of seven common diseases (including types 1 and 2 diabetes, coronary heart disease, hypertension, rheumatoid arthritis, Crohn’s disease, and bipolar disorder) and 3,000

controls (Welcome Trust Case Control Consortium 2007). This study suggested many unexpected genes underlying risk for the included diseases.

Current Knowledge

Current testing for GWA typically involves testing hundreds of thousands to millions of common SNP markers for association with disease in cases versus controls. Recent advances in microarray technologies, in which millions of SNP probes can be arranged on a single microscope slide, have allowed researchers to query these genetic markers, evenly spaced throughout the genome, in a single reaction and at relatively low cost. This allows for testing of association throughout the entire genome, without having to choose candidate loci in advance.

Many early GWA studies were plagued with difficulties which resulted in inconsistent findings. For example, overestimation of allelic effect sizes led to initial cohort sizes that were underpowered, and inadequate corrections for cryptic confounds such as relatedness and ancestry could lead to false positive findings. As these difficulties have become more appreciated and sufficiently addressed, GWA studies in several areas of medicine, including diabetes, intracranial aneurysms, and inflammatory bowel disease, have yielded reproducible results (Hindorff et al. 2011; Manolio 2010).

In autism spectrum disorders (ASD), three associated alleles, one each from three independent GWA studies, have been identified that meet accepted discovery criteria, as of December 2011: (1) an intragenic region on chromosome 5p14 between the genes *CDH9* and *CDH10* (Wang et al. 2009), (2) a region on 5p15.3 within 80 kb of *SEMA5A* (Weiss et al. 2009), and (3) an intragenic region on 20p12 within *MACROD2* (Anney et al. 2010). While each study demonstrated genome-wide significance and internal replication, none of the three studies replicate one another, and a combined analysis of data from all three studies appears to decrease evidence for association for all three alleles (Devlin et al.

2011). Despite this lack of convergence so far, it is believed that multiple common variants of very small effect remain to be identified in ASD, and increasing sample sizes may be required (State and Levitt 2011).

The current state of GWA studies in ASD illustrates an important lesson learned over the last decade for GWA studies across all of medicine: most of the variants found are associated with only a small increased risk of the disease (e.g., odds ratios of 1.1–1.5 per associated allele) and explain only a small amount of the heritability, as determined from twin studies. These modest effect sizes have little clinically useful predictive value and suggest that most GWA studies have low power to detect associations at typical sample sizes (Altshuler et al. 2008; Manolio 2010). Furthermore, the question of why so much heritability is unexplained by GWA studies has led to an increased focus on the contribution of rare and structural variants (poorly detected by currently available genotyping arrays), interactions between genes, interactions between genes and environmental factors, and studies of ancestrally diverse populations (Manolio 2010; Manolio et al. 2009).

Future Directions

With the application of rigorous methodology and large sample sizes to GWA studies in ASD, there is hope that definitive replication of common ASD alleles will emerge. This will lead to the additional challenge of translating such findings into potentially targetable neurobiological mechanisms. Even with replication, there remains the challenge of narrowing an associated locus to a single variant that is directly implicated in disease etiology, an achievement which has so far remained elusive for GWA studies throughout medicine.

Next-generation sequencing technologies are now allowing a genome-wide view of all nucleotides in the genome. As the 1,000 Genomes Project (1000 Genomes Project Consortium 2010) and other large-scale efforts aim to create an accurate map of all single nucleotide and structural variants in the genome, GWA studies may be extended to rare variants which could explain

some of the unmapped heritability in common polymorphism GWA studies.

Geodon (Ziprasidone)

Wouter Staal
Neuroscience, Radboud University Nijmegen
Medical Centre Karakter, Nijmegen, The
Netherlands

Synonyms

[Marketed as Geodon; Zeldox](#)

Definition

Ziprasidone is an atypical antipsychotic agent with a high affinity for dopamine, serotonin, and alpha-adrenergic receptors and a moderate affinity for histamine receptors. The mechanism of action of ziprasidone is unknown. Ziprasidone is a complex molecule with the chemical name 5-[2-[4-(1,2-benzisothiazol-3-yl)-1-piperazinyl]ethyl]-6-chloro-1,3-dihydro-2H-indol-2-one. Its action is thought to be caused by antagonizing dopamine receptors, especially D2. Antagonism of histaminic and alpha-adrenergic receptors may be related to adverse effects of ziprasidone, such as sedation and orthostasis.

Ziprasidone can be administered intramuscularly or orally with food. Steady-state plasma concentrations are achieved within 1–3 days with a mean half-life ranging from 2 to 5 h. Ziprasidone is largely metabolized by aldehyde oxidase and for a smaller portion by cytochrome P450 3A4

(CYP3A4). Ziprasidone has a number of adverse effects most notably including sedation, insomnia, orthostasis, life-threatening neuroleptic malignant syndrome, akathisia, tardive dyskinesia, chest pains, and impaired erectile function.

In the United States, ziprasidone is Food and Drug Administration (FDA) approved for the treatment of schizophrenia and for acute treatment of mania and mixed states associated with bipolar disorder.

Landmark Clinical, Scientific, and Professional Contributions

Dr. Geraldine Dawson's research on autism spectrum disorders has focused on early detection and intervention and elucidating the nature of brain dysfunction and development. A former Professor at University of Washington and Chief Scientific Officer at Autism Speaks, Dr. Dawson is currently the Director of the Duke Center for Autism and Brain Development at Duke University, President of the International Society for Autism Research, and a Professor of Psychiatry and Behavioral

Sciences, Pediatrics, and Psychology and Neuroscience at Duke University. Dr. Dawson's work demonstrated how maternal depression influences early brain activity and stress responses in infants and children (Dawson et al. 1992). Dawson used home videotapes to demonstrate that autism symptoms emerge during the first year of postnatal life (Osterling and Dawson 1994) and empirically validate the phenomenon of autistic regression (Werner and Dawson 2005). She published the first case study of an infant with autism (Dawson et al. 2000). Dawson demonstrated that autism is associated with early deficits in social attention (Dawson et al. 1998; Dawson et al. 2004) and proposed that such attention deficits are related to reduced sensitivity to the reward value of social stimuli ("social motivation hypothesis") (Dawson et al. 2002). Dawson's laboratory pioneered the use of electrophysiological techniques to study brain function in autism, including during early childhood (Dawson et al. 1986; Dawson et al. 1988; Dawson et al. 2002). Research in her laboratory identified autism neural signatures (event-related brain potentials in response to faces) (Dawson et al. 2002) that were later shown to be associated with early risk identification (Jones et al. 2016) and endophenotypes in relatives (Dawson et al. 2005), and used for biomarkers in autism clinical trials (Dawson et al. 2012a, b). As part of the NIMH STAART (Studies To Advance Autism Research and Treatment), and in collaboration with Dr. Sally Rogers, Dr. Dawson co-developed and empirically validated the Early Start Denver Model (Rogers and Dawson 2010; Rogers et al. 2012), the first comprehensive early intervention program for very young children with autism (Dawson et al. 2010; Estes et al. 2015). ESDM has been translated into 14 languages and is used worldwide. Her research demonstrating that early intervention based on ESDM can normalize brain activity in children with autism was recognized by TIME magazine as one of the top 10 medical breakthroughs of 2012 (Dawson et al. 2012b). Dawson has also been a contributor to several autism studies on using structural and functional MRI (e.g., Sparks et al. 2002; Friedman et al. 2007) and genetic risk factors.

Short Biography

Dr. Dawson is a licensed, practicing Child Clinical Psychologist, obtaining her PhD from University of Washington and completing her postdoctoral training and internship at the UCLA Neuropsychiatric Institute. As a faculty at the University of North Carolina and University of Washington, Dr. Dawson has trained 23 doctoral students and 5 postdoctoral fellows who have gone on to careers as clinical psychologists and university faculty. She continues mentoring students at Duke, where from 2013 to 2016, she trained 1 doctoral student, 9 postdoctoral fellows, 1 clinical psychology intern, and 2 medical students. As faculty at UW, she received continuous funding for her research from 1980 to 2008 including serving as Director for multidisciplinary center grants from the NIH Collaborative Programs for Excellence in Autism, STAART, and Autism Center of Excellence scientific programs. These multidisciplinary autism research programs focused on genetics, neuroimaging, early diagnosis, and treatment. At UW, Dr. Dawson also founded and oversaw the UW Autism Center endowed treatment center for children with ASD. At Autism Speaks, she directed \$20–30 million in annual research funding, including funding for the Autism Treatment Network, the Autism Genetic Resource Exchange, the Autism Genome Project, and the Autism Tissue Program. Under her leadership at Autism Speaks, several new initiatives were launched, including the Translational Medicine Research Initiative, Postdoctoral Research Fellowship, the Trailblazer Award, the Autism 10K Genome Project, the Early Access to Care Initiative, the Global Autism Public Health Initiative, and DELSIA (Delivering Scientific Innovation for Autism). At Duke University, Dr. Dawson is the Founding Director of the Duke Center for Autism and Brain Development at Duke University, North Carolina, which includes an integrated interdisciplinary clinical care, research, and training facility. Her current research at Duke focuses on early detection and early behavioral intervention and clinical trials testing novel molecular and cellular therapies for

autism using eye-tracking, EEG, and MRI as biomarkers and outcome measures. Dr. Dawson has published over >270 articles and 10 books on early detection and treatment of autism and brain development. She has testified before the US Senate in support of legislation for autism research funding and insurance coverage for autism services.

Germany and Autism

Sven Bölte

Center of Neurodevelopmental Disorders (KIND), Department of Women's and Children's Health and Child and Adolescent Psychiatry, Center for Psychiatry Research, Karolinska Institutet and Stockholm County Council, Stockholm, Sweden

Historical Background

Leo Kanner had studied medicine in Berlin between 1913 and 1919, got Prussian citizenship in 1920, worked at the Charité, and as a private practitioner in Berlin until 1924 (Neumärker 2003) before immigrating to the USA. His concept of autism (Kanner 1943) was introduced to Germany shortly after World War II by Hermann Stutte, a child and adolescent psychiatrist from Marburg, who had exchange with Arn Van

Krevelen, a Dutch child and adolescent psychiatrist from Leiden who was among the first Europeans to confirm the condition in the early 1950s (Van Krevelen 1952a, b). During the same time psychiatrist Gerhard Bosch described the first cases of autism in Frankfurt, particularly focusing on language development issues and the differentiation of autism and schizophrenia. His book “Infantile autism: A philosophical study of the languages of autism” was published in 1962 (in English 1970) and includes thoughtful and empathetic case descriptions together with many valuable novel insights such as a discussion of the differences and similarities between Kanner’s and Hans Asperger’s (1944) descriptions and a need to broaden the concept of autism, long before the term Asperger syndrome and autism spectrum were coined. Bölte and Bosch (2004, 2005) followed up on Bosch’s cases 40 years after initial diagnosis. In the 1970s, Doris Weber from Marburg studies autism in relation to Heller’s dementia infantilis (1908) [childhood disintegrative disorder], a diagnosis often given to children with autism at that time in Germany, while Gerhardt Nissen in Würzburg studied Kanner’s and Asperger’s description versus psychogenic and somatic forms of autism. The concept of Asperger syndrome was not used frequently in Germany before the early 1970s. While until the later 1970s, autism was still widely considered an infantile psychosis and psychoanalytic views were also still influential, it is today widely accepted among many professions that autism is a brain-based developmental disorder of multiple genetic and environmental origin. The understanding of autism being a spectrum disorder was well established before the release of DSM-5 (American Psychiatric Association 2013). Autism awareness and services in many parts of the society and among clinical professionals working with adults have gradually developed in recent years. National clinical guidelines for the assessment of autism spectrum disorder have recently been updated by the German Society of Child and Adolescent Psychiatry and Psychotherapy and the German Association for Psychiatry, Psychotherapy, and Psychosomatics (<http://www.awmf.org/leitlinien/detail/II/028-018.html>).

Legal Situation

The Social Security State Book came into effect in 2001, entailing rules for rehabilitation and participation for individuals with disabilities. The Federal Act of Equal Opportunities was released in 2002 aiming to achieve equal opportunities for people in public space (“accessibility”). The General Equal Treatment Act came into effect in 2006 and comprises among other things the equalization of people with disabilities in the area of the civil law. The United Nations convention on the rights of people with disabilities was ratified in 2006. For the state, counties and municipalities, administrations and courts, these guidelines are now applicable law, and all national laws need to be interpreted in the light of the UN convention. The degree of disablement and the entitlement are connected to the International Classification of Diseases (ICD-10, WHO 1992) codes for different forms of autism spectrum disorder (F84.0, F84.1, F84.5). Thus, an ICD-10 diagnosis is required before an assessment of the degree of disability which is a prerequisite for access to additional clinical and other services. The assessment of the degree of disability is complex and often lengthy and is reassessed with varying intervals.

The Social Security State Book and The General Equal Treatment Act include several support means for people classified as having different degrees of disability, for instance, additional autism-specific individual intervention in addition to medical treatment; speech, language, and occupational therapy; integration aids for kindergarten and school; and further education and employment. It also comprises costs for traveling, a study assistant for structuring and orientation, and assistive technologies. In case of a high degree of disability there are several options for sheltered or supported/integrated employment. In long-term full support residential care, the complete basic needs are covered, plus pocket money. In partly supported homes, people with autism cover the costs for food, clothing, and rent themselves by their salary or different forms of relief payments. Caregivers can apply for care insurance payments for supporting their child if they

compensate for the individual with autism's disabilities, instead of using public services. In this case, the medical service of the statutory nursing care insurance decides on the degree of an individual's disability based on physician and nurse assessments. Another option is the so-called personal budget that was released in 2008, where a social service may not only be given as a traditional benefit in kind, but a payment or voucher to a caregiver. This gives the possibility to caregivers to decide themselves which help they want to provide to their child. For parents of children with autism it is also recommended that they do a "disabled testament" in order to ensure that after their deaths the complete heritage is not transferred to the welfare agency, so that their offspring can still receive care beyond livelihood using the heritage. Currently, a new regulation, the Federal law of integration and participation, is under negotiation, planned to come into effect January 1, 2017. While it is aiming to improve the inclusion of individuals with functional disabilities, its draft has caused considerable concerns about weakened access to services for individuals with autism.

Development of Services

In the beginning, individuals diagnosed with autism were treated at university hospitals and then referred to institutions for long-term residential care, mostly designed for intellectual disability care. As autism was rarely diagnosed until the later 1960s, there was little apparent need or interest for specialized care for autism. The Max-Planck Institute of Psychiatry Research in Munich introduced behavior therapy to autism influenced by US American developments. Like in other countries, a major breakthrough for autism was achieved in Germany by an emerging engagement of parents trying to get adequate diagnostic assessment and treatment for their children with mostly severe forms of autism. In 1970, "Hilfe für das autistische Kind" (today renamed in "Autismus Deutschland"; www.autismus.de) was founded. During this time, many parents sought advice from Hans Kehrner, child and adolescent

psychiatrist in Münster, who also had published the first articles on behavior therapy for social and language difficulties in autism (Kehrner and Körber 1971; Kehrner and Budde 1972) and the first comprehensive text book on autism (Kehrner 1978). The parent society developed rapidly and started to establish autism therapy centers favoring family work, the upcoming TEACCH approach, and behavior modification, but also a variety of alternative forms of intervention. Today, more and more special school classes and even occasionally regular schools provide day care and inclusive teaching for children with autism. A range of academic and municipality hospitals have established autism centers, specialized day care units, or outpatient department for autism assessment and intervention aiming to follow evidence-based best practice principles. There is also a clear tendency to accomplish early diagnosis of autism and treatment in child and adolescent psychiatry. Even many private practitioners offer autism-specific services, some center-like organizations offering particular forms of intervention only, such as Applied Behavior Analysis, TEACCH, PECS, or social skills training. In the last decade, services for adults with autism spectrum disorder have started to improve in clinical settings, but also in other fields of society (e.g., employment, living). For instance, the psychiatry departments at the universities in Freiburg and Cologne run specialized departments for higher functioning autism. Most of this development is driven by increasing diagnoses rates of autism among adults and a previous lack of autism expertise among professionals in the adult mental health field, but also by the increasing voice of the neurodiversity and empowerment movement, for instance organized within the "Aspies e.V., Menschen im Autismus-spektrum" (www.aspies.de).

Research

Autism science has developed considerably in Germany in the last decade. For instance, while in the year 2005 only 19 original articles (cited in PubMed) on autism were published with a

German academic affiliation, the number was 171 in the year 2015. Many German clinics and labs are today involved in European and international autism research collaborations and projects, such as the European Collaboration in Science and Technology (COST) activity “Enhancing the Scientific Study of Early Autism” (www.cost-essea.com), EU-AIMS (www.eu-aims.eu), European Autism Interventions – A Multicentre Study for Developing New Medications – the largest single grant for autism in the world, and the largest for the study of any mental health disorder in Europe, or The Autism Genome Project (www.autismspeaks.org/science/initiatives/autism-genome-project). Universities that are particularly active in autism research are Aachen, Berlin, Cologne, Frankfurt, Freiburg, Mannheim, and Marburg. In 2008, the Scientific Society Autism Spectrum (WGAS) ([www.wgas-autismus.org](http://wgas-autismus.org)) was established. The WGAS is devoted to supporting basic and applied autism research primarily in Germany, Switzerland, and Austria. Among other things, the WGAS meets this goal through producing scientific publications, facilitating annual events such as the Scientific Meeting for Autism Spectrum Conditions (WTAS) (<http://wgas-autismus.org/meeting-wtas>), promoting networking among colleagues active within the autism field, and the formation of professional groups. WGAS also provides training and continuing education for researchers, support for junior scientists, and sponsorship of awards for outstanding research contributions.

Training

The majority of autism specific training in Germany is still conveyed via postgraduate courses, predominantly by autism therapy centers or private providers. Such education often focuses on applied intervention techniques, such as ABA, TEACCH, PECS, and social skills training but also and autism assessment and other preclinical and applied areas. Autism often only plays a minor role in the comprehensive postgraduate curricula to accomplish approximation for being a certified psychotherapist. Clinical ADOS training is offered by several

academic child and adolescent psychiatry departments. Some higher education departments have established autism-specific modules or curricula for students, such as the Department of Psychology and Pedagogics at Ludwig Maximilian University Munich, The Jacobs University in Bremen, and the University of Applied Science in Münster.

Gesell, Arnold

W. Thornton N. Deegan
Yale Child Study Center, New Haven, CT, USA

Name and Degrees

- Gesell, Arnold Lucius (June 1, 1880–May 21, 1961).
- Arnold Gesell received his B.Ph. in 1903 from the University of Wisconsin and his Ph.D. in Education in 1906 from Clark University. In 1911, Gesell accepted an assistant professorship at Yale University, teaching graduate courses in education while working toward his M.D., which he received in 1915.

Major Appointments (Institution, Location, Dates)

- Stevens Point High School, Stevens Point, WI, 1899–1901, Teacher of US history, ancient history, German, accounting, and commercial geography.
- Chippewa Falls High School, Chippewa Falls, WI, 1903–1904, Principal.
- Los Angeles State Normal School, Los Angeles, CA, 1908–1910, Professor of Psychology.
- Yale University, New Haven, CT, 1911–1948, Assistant Professor of Education, Professor of Education, Professor of Child Hygiene, Founder and Director of the Yale Psycho-Clinic (later renamed Yale Clinic of Child Development, later renamed Yale Child Study Center), Professor Emeritus of Child Hygiene.
- Connecticut State Board of Education, Hartford, CT, 1915–1919, School Psychologist.
- Connecticut Commission on Child Welfare, Hartford, CT, 1919–1921, Member.
- American Psychological Association, Washington, D.C., 1922–1936, Director.
- American Child Health Association, 1928–1940, Director.

- New Haven Hospital, New Haven, CT, 1928–1948, Attending pediatrician.

Major Honors and Awards

Dr. Gesell received numerous honors and awards during his lifetime. Among them are honorary Doctor of Science degrees from Clark University (1930) and the University of Wisconsin (1953). The Gesell Institute of Child Development is named in his honor.

Landmark Clinical, Scientific, and Professional Contributions

Dr. Gesell is most renowned for his Developmental Schedules, which track the behavioral development of typical children through the first few years of life. Dr. Gesell was also known for his groundbreaking observational methods, pioneering the use of cinematography, still photography, and one-way vision screens to observe subjects without disrupting them. Cinematography especially provided a way to reproduce nuances of behavior faithfully and completely for later analysis. Through his professional contributions, Dr. Gesell helped establish child development as a scientific field, effectively bridging the gap between psychology and pediatrics.

Short Biography

Arnold Gesell was born on June 21, 1880, in the small town of Alma, located on the western edge of Wisconsin, on the eastern bank of the Mississippi River. Gesell's father, Gerhard, was a photographer with a studio in Alma and had a great interest in education, and Arnold's mother, Christine, was an elementary school teacher. Arnold was also the first of five children, with two brothers and two sisters. This family upbringing had a tremendous effect upon Arnold. Experiencing childhood with a family

background in education, in the presence of other children, led Arnold to be fascinated with childhood, education, and growing up, and more specifically with the experiences of those who deviated from what was considered normal. This in turn led him to study education and psychology, that he might better understand the mechanics of human development. Gesell attended the University of Wisconsin, receiving his B.Ph. in 1903, thereafter serving as principal at Chippewa Falls High School in Chippewa Falls, Wisconsin, for 1 year before attending Clark University in Worcester, Massachusetts. Here he met G. Stanley Hall, who advocated the investigation of the mental traits and abilities of children, which left a distinct impression on Gesell long after he received his Ph.D. in Education from Clark in 1906 and left to further his career. It was G. Stanley Hall's influence, perhaps more than any other, that ignited Gesell's interest in child development and which would last him the rest of his career.

In 1911, Gesell accepted an assistant professorship at Yale University, teaching courses in education at the graduate school while simultaneously enrolled at Yale Medical School. In the same year, he founded the Yale Psycho-Clinic, which is now the Yale Child Study Center. He received his M.D. in 1915, and in the years that followed began expanding his work at the Psycho-Clinic. Dr. Gesell's primary interest was intellectually disabled children; however, he realized that an understanding of what constituted "normal" was essential to understanding "abnormal." Dr. Gesell hypothesized that normal human behavior develops in a systematic, patterned way and can therefore be charted. Dr. Gesell, drawing on inspiration from his father, introduced cinematography as one of the main observational tools used for research at the Clinic. Using this and other groundbreaking tools and methods, Dr. Gesell produced the Gesell Developmental Schedules, which illustrated general patterns and stages of normal behavioral development. Arnold Gesell was also noteworthy for his extensive studies with twins and also for being vocal on issues related to education and family welfare. A prolific

writer, Dr. Gesell published numerous books and scientific articles on a variety of subjects, from social and family issues to developmental diagnosis. Dr. Gesell served as Director of the Yale Child Study Center until 1948, when he retired and became professor emeritus. Milton J.E. Senn, M. D, superseded him in his role as Director of the YCSC. He died in 1961.

Gestural Imitation

► Body Movements, Imitation of

Gesture Form and Function in ASD

Ashley B. de Marchena
Department of Behavioral and Social Sciences,
University of the Sciences, Philadelphia,
PA, USA

Definition

Communicative co-speech gestures are spontaneously produced body movements (primarily hand movements) that occur during fluent speech and add both semantic and pragmatic content to communication.

Historical Background

Differences in co-speech gesture production have been clinically observed since Kanner first described autism in 1943 (► [Kanner, Leo](#)).

Current Knowledge

Impairments in nonverbal communication (including gesture) are required for a diagnosis of autism spectrum disorder (ASD), and the absence of early gestures is considered a red flag for ASD in toddlers. Despite their clear relevance to social-communication functioning, gestures produced during the context of developed, fluent speech have received limited empirical attention. This entry reviews what is known about both the *production* and *comprehension* of these *co-speech gestures* in verbally fluent children, adolescents, and adults with ASD.

Gesture Versus Speech: How Does Gesture Communicate?

Speech and gesture both convey meaning but in different, complementary formats. Speech conveys information in discrete/digital units (i.e., words) that are culturally defined and consistently used to mean the same thing across contexts (i.e., consistent semantics). Speech presents this information in a linear, sequential format (i.e., consistent syntax). In contrast, gestures are “global-synthetic: a representation that is not divided into parts but rather captures the whole of the referent” (Goldin-Meadow and Alibali 2013). Further, whereas the meaning of words is almost always arbitrarily related to their sound, the meaning of gesture is often directly related to its form (i.e., iconicity). As an example, imagine a child describing a roller coaster: “first it went up up up, then it slowed down, then we shot back down to the ground and went around and around!” In speech, this information must be conveyed one unit at a time and combined using the rules of syntax. Now picture the gestures that might accompany this description – they are likely portrayed continuously across the entire utterance, *showing* the roller coaster as a whole, and incorporating multiple features at once, including shape, speed, and direction. Note also that the child’s gestures are likely to portray information that may be absent or difficult to describe in speech. For example, in what way did the roller coaster go around and around? Was it a loop-de-loop, or was it a flat circle parallel to the ground? This information, while clunky and complicated to describe in speech, is likely to be automatically enacted in gesture as the child’s visual representation of the roller coaster spills out into their hands (i.e., Hostetter and Alibali’s “gesture as simulated action” framework). For an excellent review on the role of gesture in speaking and learning in typical development, see Goldin-Meadow and Alibali (2013).

Gesture benefits communication both by supporting and elaborating information conveyed in speech and also by engaging listeners’ attention and interest during discourse; thus, gestures alter and enhance the communicative signal, both by adding *content* to the discourse and by adding

social structure to the discourse. Although debated, most gesture theorists believe that gesture and speech are fundamentally part of the same system; thus, to truly understand gesture production and comprehension, it must be studied within the context of its integration with speech. Accordingly, the current entry reviews only research that includes both modalities, across both production and comprehension.

Gesture Production in ASD

There are at least three reasons why the field should care about understanding gesture production in ASD during developed, fluent speech: (1) co-speech gestures enhance the communicative signal, (2) co-speech gestures benefit a speakers' own cognitive processes, and (3) co-speech gestures may provide a means for elucidating qualitative differences in behavior in ASD that have been challenging to describe and quantify. These are reviewed below.

Co-speech Gestures Enhance the Communicative Signal

From the perspective of production, one way to look at how much content gesture adds to speech is simply to look at the *rate* of gestures produced over a discourse (i.e., gestures per minute/word/utterance). Gesture rate is often assumed to be reduced in ASD throughout the lifetime, because reductions in gesture are such a prominent sign of ASD in toddlers. In fact, gesture rate does *not* appear to be consistently reduced in verbally fluent children, adolescents, and adults on the autism spectrum. While a number of studies have demonstrated small reductions in gesture rate across different kinds of tasks (de Marchena and Eigsti 2014; Medeiros and Winsler 2014; Silverman et al. 2017; So et al. 2014), many studies have failed to demonstrate group differences in case-control studies using similar tasks (Attwood et al. 1988; Capps et al. 1998; de Marchena and Eigsti 2010; de Marchena et al. 2018; Hobson et al. 2010; Morett et al. 2016; So and Kit-Yi Wong 2016). Taken as a whole, the literature suggests that gesture rate may be slightly reduced in ASD, but not enough to account for the very noticeable differences in gesture production

that have long been reported by clinicians. So if rate does not adequately portray the picture of atypical gesture in ASD, let us now turn to *what* gesture communicates.

Gestures add *content* to verbal interactions in multiple ways. Gestures can add concrete visuo-spatial information to speech (e.g., imagine someone describing a tiny egg they found on a hike while holding their finger and thumb a half-inch apart). They can add emphasis or signal uncertainty. They also serve critical pragmatic functions that are often overlooked, such as linking the context of the physical environment to the contents of speech, thereby allowing listeners to make inferences about a speaker's intended meaning (e.g., imagine a speaker who says "wow, it's getting stuffy in here" while pointing at a window near you; Kelly et al. 1999).

The functions and meanings of gestures are typically quantified by categorizing gestures into distinct "types"; there are multiple systems for this. Categorizing gesture presents certain challenges, as gesture is a holistic, analog system that does not categorize easily. The first study to look at gesture production in ASD across different types of co-speech gestures (Attwood et al. 1988) found differences in the types of gestures produced; specifically, adolescents with ASD did not use *expressive* gestures (i.e., gestures making reference to emotions or other internal states), but were comparable to controls in their use of pointing and instrumental gestures. People with ASD may use more *iconic* gestures (i.e., gestures depicting physical aspects of a referent, such as shape, size, or motion; "descriptive" gestures on the ADOS) than controls (Morett et al. 2016; So and Kit-Yi Wong 2016), perhaps because enacting experiences is more accessible than verbalizing them (Capps et al. 1998). However, not all studies find an increased rate of iconic gesture production in ASD, and some studies find no difference in gesture types at all (de Marchena and Eigsti 2010; Silverman et al. 2017).

In addition to conveying specific content, gestures also add *social structure* to the discourse. For example, gestures may be used to cite another person's contribution to the conversation (e.g., an open palm moving toward an interlocutor could

be translated as, “like you said earlier”); to signal agreement, disagreement, hesitation, or emphasis; and to regulate turn-taking dynamics (e.g., “you go ahead,” or “I’m still talking”). Thus, gesture helps structure the interaction itself. Autistic adults have been found to use these “interactive gestures” (Bavelas et al. 1992) *more often* than controls, particularly to help regulate conversational turn-taking, suggesting again that gesture may be a particularly accessible communicative modality (de Marchena et al. 2018).

Gesture can also structure a conversational exchange through the use of *anaphor*, in which a physical area within the gesture space is used to consistently refer to a specific referent within a discourse (e.g., when talking about two friends, whenever I talk about *Sadie*, I always gesture toward my upper right, but when talking about *Oliver*, I always gesture toward my upper left). During an explanation task, children with ASD were found to be internally consistent in their own use of anaphor; however, when an examiner suggested specific locations for referents by using anaphor herself (e.g., the toothbrush is on the right, the toothpaste is on the left), children with ASD were less likely to adopt the spatial locations indicated by the examiner (So and Kit-Yi Wong 2016) relative to controls. This suggests weaknesses in attending to others’ gestures and subsequently incorporating that information into one’s own communication, which could easily lead to communication breakdowns. On the other hand, there is some evidence that individuals with ASD intend for at least some of their own gestures to be communicative. Like controls, adolescents with ASD produce more gestures when in the presence of a visible listener (Morett et al. 2016), suggesting that they recognize the communicative benefits of gesture and do not simply gesture to facilitate their own cognitive processes.

Co-speech Gestures Benefit a Speakers’ Own Cognitive Processes

In addition to its social-communicative power, gesture also confers a range of benefits for speakers themselves. Some of these benefits relate directly to communication: for example, gesturing

can help speakers plan and organize the contents of a story. The act of gesturing can also help facilitate word finding; indeed, when speakers are prevented from gesturing, they are less likely to recover from tip-of-the-tongue experiences. In addition to these communication-relevant benefits, gesture also facilitates cognitive processes that are relatively independent of communication, such as working memory and spatial reasoning. Strikingly, gesture can cause knowledge change – either directly (the act of gesturing can cause cognitive change, such as learning a new mathematical concept) or socially (gesture can convey information about a speaker’s readiness to learn and current knowledge state, allowing teachers or therapists to tailor their instruction in the moment). In the only study to probe gesture’s benefits on cognition in ASD, gestures produced by adolescents with ASD were measured during both a storytelling task and an executive function task. Teens with ASD produced fewer gestures than controls during the storytelling task (in which gestures serve a range of social-communication functions) but *more* gestures during the executive function task, in which gestures are more likely to support cognitive processes such as visual attention and concentration (de Marchena and Eigsti 2014). These findings suggest that gesture *does* convey cognitive benefits for speakers with ASD.

Co-speech Gestures May Elucidate Qualitative Differences in Behavior in ASD

Finally, the way in which co-speech hand gestures are produced by speakers may provide an assay for measuring qualitative features of behavior that have thus far proved difficult to quantify in ASD. Per DSM-5 (American Psychiatric Association 2013) criteria, nonverbal communication in ASD is defined both in terms of *quantity* (i.e., “total lack of...”) and *quality* (i.e., “abnormalities in...”). As reviewed above, by many concrete/objective measures, gesture production in ASD is quite similar to gesture production by controls: gestures are produced at a similar rate and for roughly the same purposes. Yet this similarity is quite inconsistent from clinical impressions, which often report large differences in how people

with ASD gesture, and, accordingly, with clinical measures. Quantity of nonverbal communication is relatively well-characterized on ASD questionnaires. The Autism Diagnostic Observation Schedule (► [Autism Diagnostic Observation Schedule](#)), a clinical observational tool, prompts clinicians to attend to both quality and quantity of different gesture types. However, the specific ways in which gestures might differ qualitatively in ASD have yet to be adequately characterized empirically.

Two studies have looked at how gesture production affects overall communication quality. de Marchena and Eigsti (2010) recorded adolescents with ASD telling the “Monkey” cartoon from the ADOS, in which participants were prompted to tell a story based on six black-and-white line drawings. They then played recordings of these adolescents to diagnosis-naïve college students either with or without video (i.e., audio only). Controls were rated as telling higher quality stories in the video condition (i.e., when raters could see them); in contrast, teens with ASD were rated as telling higher-quality stories in the audio-only condition. This suggests that something about the gestures, facial expressions, or general movements produced by autistic teens may have been distracting to observers, whereas these behaviors benefited communication in controls. Similarly, Morett and colleagues (2016) found that quality ratings for stories produced by teens with and without ASD differed when participants were speaking to a visible interlocutor, but did not differ when told to a hidden interlocutor (and participants were therefore using fewer non-verbals). Morett and colleagues further found that features of speech, gesture, and speech-gesture combinations predicted communication quality in controls, whereas *only speech* predicted communication quality in teens with ASD, suggesting once again that gesture does not benefit communication to the same extent in ASD.

As described above, gestures are often used at the same rate, and for similar communicative functions, in ASD. So why are they not benefiting communication to the same extent? Several studies have now looked at the quality of each individual gesture produced within a discourse and

consistently found large group differences in children, adolescents, and adults on the spectrum (de Marchena et al. 2018; Hobson et al. 2010; Hobson and Lee 1998; Silverman et al. 2017). Group differences have been identified in terms of (1) the physical form of the gesture (Hobson et al. 2010; Hobson and Lee 1998), (2) the clarity of the gesture as a communicative act (i.e., whether a movement was a gesture or not; Silverman et al. 2017), and (3) the intended meaning or purpose of the gesture (de Marchena et al. 2018; Silverman et al. 2017). Further supporting the claim that qualitative features of gesture may better describe ASD, Silverman and colleagues (2017) found that qualitative features of gesture predicted clinical measures (e.g., ADOS scores), whereas gesture rate did not. Further research is needed to understand how these differences may be related within individuals with ASD (e.g., are atypically formed gestures harder to identify as acts of communication)?

So what about gesture in ASD leads to reduced quality and, in turn, less communicative power? More research is needed to answer this question and to point to new possible targets for intervention. One possibility is that gestures are less well-integrated into speech, making it less clear that gesture and speech represent a unified package of meaning. In fact, gesture and speech are less temporally synchronous in ASD (de Marchena and Eigsti 2010; Morett et al. 2016), and the degree of asynchrony between speech and gesture predicts observers’ ratings of communication quality (de Marchena and Eigsti 2010). Observed differences in speech-gesture synchrony are consistent with the growing literature on difficulties with multimodal integration in ASD. Second, atypicalities in gesture may be secondary to motor skills differences in ASD that are now widely understood to be part of the behavioral phenotype. Specifically, difficulties with *praxis* (► [Praxis](#)), or the ability to perform skilled movements, are strongly theoretically linked to co-speech gesture production, particularly when considering gestures that involve motor enactment of visuospatial features, such as shape or motion. The relationship between gesture and praxis, or motor behavior in general, has not yet been directly tested.

Hobson and Lee (1998), who reported a decreased rate and quality of spontaneous greeting/farewell waves in ASD, informally described the waving as “ill-directed, perfunctory, or clumsy and limp” (Hobson and Lee 1998, p. 124), consistent with a wide range of possible social-motor differences and consistent with stakeholder reports that gestures in ASD are often produced in surprising or odd ways (e.g., pointing with the middle finger, which can run the risk of the occasional faux pas!).

Gesture Comprehension in ASD

For neurotypical individuals, gestures facilitate comprehension both by enhancing information already conveyed in speech and by communicating information that goes beyond speech. The small literature on gesture comprehension in ASD supports the conclusion that bimodal processing (i.e., comprehension of speech-gesture combinations) is slowed and inefficient in ASD, despite relatively intact accuracy on structured tasks. People with ASD thus may benefit less from gestures during spontaneous conversation, even if they are able to parse gestures themselves when given enough time. For example, when given instructions presented in both speech and gesture, both adolescents (Silverman et al. 2010) and adults (Canfield et al. [under review](#)) with ASD are slower to process these speech-gesture combinations compared to controls. This effect is particularly strong when the information presented in gesture is incongruent with the information in speech (Canfield et al. [under review](#)), suggesting that autistic adults may prioritize the verbal modality over the gestural modality. However, slowed processing is found even when speech and gesture present the same information, for example, saying “find the loop,” while tracing a loop with a finger. In fact, controls tend to be faster to respond when presented with semantically congruent information across speech and gesture, whereas teens with ASD respond more quickly when information is presented in the audio channel only. These findings suggest that individuals with ASD are slowed by the additional processing demands of incorporating gestural information (Silverman et al. 2010), even when

this information is semantically identical to speech. Neural processing of communicative co-speech gestures also appears to be atypical in ASD. In the only fMRI study of co-speech gesture in ASD (Hubbard et al. 2009), participants passively viewed videos of people talking either with or without accompanying beat gestures (i.e., gestures conveying emphasis, with little to no specific semantic content). Typical children showed increased activation of the superior temporal sulcus while viewing beat gestures, suggesting that they interpreted these movements as communicative; children with ASD, on the other hand, increased visual cortex activation, suggesting that while they viewed the movements as visually salient, they did not automatically interpret them as a signal relevant to communication.

These differences in gesture processing, which have been observed across measures of reaction time, eye tracking, and fMRI signal, are in sharp contrast to gesture comprehension *accuracy* in ASD on behavioral tasks, which is generally strong. Children with ASD are able to understand deictic, iconic/descriptive (Dimitrova et al. 2017), and emblems/conventional gestures (Attwood et al. 1988) on structured tasks. Likewise, adults with ASD are as accurate as controls at identifying whether an iconic/descriptive gesture matches a target action (e.g., chopping; Canfield et al. [under review](#)). Comprehension accuracy may be reduced when gestures are unexpected or atypical (e.g., nodding the head toward an object instead of pointing at it; Hobson et al. 2010). A major limitation of the comprehension literature thus far is that it has been conducted exclusively with relatively simple, trial-by-trial, highly structured tasks. To date, just one study provides a hint at what gesture comprehension in ASD looks like in a more naturalistic setting. Using a problem-solving task that parents and children completed together, Medeiros and Winsler (2014) found that in controls, parents gestured more when their kids weren’t as good at the task, but this relationship not observed in ASD. This suggests that parents of neurotypical children perceive that their kids benefit more from nonverbal communication support, which is not assumed by parents of children with ASD.

Future Directions

As reviewed above, by many concrete/objective measures, gesture production in ASD is quite similar to gesture production by controls: gestures are produced at a similar rate, and for roughly the same purposes. This is quite inconsistent from clinical impressions and established clinical instruments, which often report large differences in how people with ASD gesture. In contrast, qualitative differences in how gesture is performed or integrated into conversation are robust; understanding the nuance of these differences will lead to a richer understanding of communication in ASD. One potential starting point is testing the relationship between gesture production and motor skills in ASD.

With respect to comprehension, much more information is needed to truly understand how people with ASD process and understand gestures in the real world. Accuracy may be relatively high in ASD, when there is enough time – and when gestures are tagged by an experimenter as semantically relevant. However, the real world moves fast, and observed inefficiencies in processing suggest that gesture may often be left behind. Ultimately, we must understand and intervene at the level of the real world; thus, naturalistic research is needed to push the field forward and pave the way for interventions to improve non-verbal communication in verbally fluent individuals on the autism spectrum.

Definition

Gestures are actions produced with the intent to communicate. Gestures can involve fingers, hands, arms, facial features, or the entire body (Iverson and Thal 1998). When these actions are performed with the purpose of affecting another person's behavior, they are considered to be intentional communication acts (Bates 1976). Intentional use of gestures develops before speech and continues to develop as the child's speech emerges (Iverson and Thal 1998).

Gestures can be organized according to their purpose or communicative function. Bruner (1981) classified gestures according to three broad categories based on functions: social interaction, behavior regulation, and joint attention. Differences have been found in the gesture development of children later diagnosed with autism spectrum disorders (ASD).

Social interaction gestures are used to initiate or maintain the attention of another person in a social experience. These gestures might include waving "hi" or "bye," requesting games or routines, and shaking the head for "yes" or "no." In their sample of 9–12-month-old infants, Colgan et al. (2006) examined the emergent use of social interaction gestures in infants later diagnosed with autism. They found that types of gestures used were strongly associated with autism status, suggesting that the examination of the number of different gestures in a child's repertoire may be useful for detecting impairments in their language development.

Behavior regulation gestures manage the behavior of others, such as requesting an object, getting another person to do something, or getting another person to stop doing something. In studies of the communicative functions of gestures, children with autism show relative strengths in the use of gestures serving the function of behavior regulation at preschool age (Mundy et al. 1990) and at school age (Wetherby and Prutting 1984).

Gestures used to establish joint attention direct another person's attention to an object or event and usually include manual pointing or making eye contact with an object. Children with ASD demonstrate significant weaknesses in the use of gestures for the purpose of joint attention (directing another's attention or sharing interest with another person) both at preschool age (Mundy et al. 1990) and school age (Loveland and Landry 1986).

Definition

Giftedness refers to high values in the distribution of skills fundamental to human accomplishments. Intelligence, talent, and creativity are neighboring but distinct notions. Whereas domain-general giftedness partially overlaps with the notion of *intelligence*, domain-specific giftedness calls its nature into question, and there is no single

intelligence-test-based threshold which consensually defines giftedness. *Talent* describes the outcome of giftedness in actual accomplishments, which depends on a combination of giftedness, training, and more or less optimal conditions for the acquisition of expertise. *Creativity* designates the capacity for innovation, which may or may not be associated with giftedness, and does not overlap with intelligence. Giftedness includes a genetic and/or innate component in the form of an overrepresentation of giftedness within some families or in the form of genetic variation favoring atypical information-processing abilities.

The association between giftedness and autism is multifaceted. First, giftedness has been associated with a certain number of psychological particularities, including an overattention and emotional reactivity to the surrounding world, a tendency to interact with older peers, indifference toward social conventions, etc. Some of these particularities overlap with the autistic phenotype and may be difficult to separate. Second, the distribution curve of autistic intelligence features higher variance than that of nonautistic individuals, such that some autistics present extreme values of general intelligence, or “double exceptionality.” Third, autistic peaks of ability, or domains where autistics as a group perform at a superior level than their IQ (as measured with certain instruments) would have predicted, represent a “group giftedness” in the form of an innate advantage for certain cognitive operations. Peaks of ability represent the main element which makes the giftedness versus autism distinction difficult in clinical settings. For example, an advance of 2 years in word-decoding skills may announce an autism diagnosis, giftedness without autism, or a combination of both. Finally, savant syndrome is strongly associated with autism and is defined by the presence of exceptional performance in neurodevelopmental variants. All possible combinations of giftedness, intelligence, talent, and autism may be manifested in savant syndrome. The range of tasks for which savants display giftedness is variable, with some savants possessing multiple areas of excellence, combined or not with deficits in other areas.

The degree, adaptive value, recognition by others, eventual outcomes, etc., of talent arising

from giftedness in autism all vary to the extreme.

Description

The Gilliam Autism Rating Scale is a standardized instrument for the assessment and diagnosis of autism and other behavioral conditions (GARS). It relies on parental or teacher reports regarding the child's presentation and behavior and is a quick measure to administer. Furthermore, no significant training is necessary. Nonetheless, some studies suggest a tendency to "miss" children who would otherwise meet the diagnostic criteria for an autism spectrum disorder (Lecavalier 2005; South et al. 2002).

The scale was revised (GARS-2) in 2006 and based on the *DSM-IV-TR* (American Psychiatric Association 2000) and *Autism Society of America* definitions of autism. The core items (42) on the three subscales were retained in the revised version, although some minor changes in wording were made.

The GARS-2 relies on parental rating of directly observed behaviors and developmental history of delay or abnormality.

The instrument is comprised of three subscales, namely, *Stereotyped Behaviors*, *Communication*, and *Social Interaction*. Instructions are straightforward and require the clinician/parent to rate a number of items according to the frequency with which the behaviors occur. Ratings are presented in a Likert style, from 0 (never observed), 1 (seldom observed), 2 (sometimes observed), to 3 (frequently observed). Additional guidance/example is provided for each rating, i.e., sometimes observed – individual behaves in this manner 3–4 times per 6-h period. Behavior is rated under typical circumstances, for instance, in the presence of familiar people, in usual places, and during day-to-day activities. Scores are summed to yield a total raw score for *Stereotyped Behaviors*.

The *Communication Subscale* and *Social Interaction Subscale* are completed in the same manner, i.e., on the basis of behaviors observed by the parent/caregiver. However, if the individual does not have speech and does not sign or use other forms of communication, the former is omitted. A total raw score is derived by summing the ratings on each subscale (14 items each). Raw scores on individual subscales are converted to

standard scores and represented as percentiles. Total standard scores for all 42 items yield a sum of standard scores. This is represented as an Autism Index and corresponds to a given percentile. The response booklet allows the plotting of the individual's profile. Furthermore, interpretation of standard scores and the Autism Index yields three possible outcomes with respect to a diagnosis of autism: *very likely*, *possibly*, and *unlikely*.

Information from parental interviews relates specifically to *delays* and *abnormal functioning*. This data may be gathered at interview or be completed by a parent directly. Responses take the form of *yes* or *no*. The questions relate to delays in social interaction and language used in social communication, specifically during the first 3 years of life. Abnormal functioning within the first 3 years of life in social interaction, language used in social communication, and symbolic or pretend play is assessed in the subsequent section. A *no* response to any of these questions indicates that the individual meets the *DSM-IV-TR* criteria for *delays* or *abnormal functioning*.

Additional questions are presented in the response form for the benefit of the clinician when reflecting on the GARS-2 results and considering the diagnostic outcome.

The measure was revised again in 2013 (GARS-3) with items reflecting the updated autism diagnostic criteria (DSM-5) (American Psychiatric Association 2013). A further four items have been included, and the GARS-3 is comprised of six subscales (total of 58 items), viz., Restricted/Repetitive Behaviors (13), Social Interaction (14), Social Communication (9), Emotional Responses (8), Cognitive Style (7), and Maladaptive Speech (7). The examiner/practitioner can use the interpretation guide to score and conclude probability and severity of ASD. DSM-5 criteria are included in a diagnostic validation form to confirm that criteria are met.

Historical Background

A number of screening and diagnostic measures for autism spectrum disorders have been developed in the past two decades. The Gilliam Autism

Rating Scale (GARS, Gilliam 1995) was initially developed as a screening measure to identify individuals with autism in research and clinical settings. Although it was widely used, there was little empirical evaluation of the measure and its usefulness (Lecavalier 2005; Mazefsky and Oswald 2006; Pandolfi et al. 2010; Norris and Lecavalier 2010).

Gilliam 2006; Eaves et al. 2006; Schopler et al. 1980; and Ehlers and Gillberg 1993 revised the original instrument retaining most of the items on the three subscales but adding a section (25 items) relating to delays or abnormalities during the first 3 years of life. The scoring system was changed, and the total score, namely, the Autism Quotient (AQ), was replaced by an Autism Index (AI).

The purpose of the GARS-3 is to assist teachers, parents, and clinicians in identifying and diagnosing autism in individuals from 3 to 22 years of age. Furthermore, consistent with GARS-2, the revised tool aims to provide information regarding *severity* of the condition. The GARS-3 may also be used to rate change, and the manual provides examples of discreet target behaviors for all items which may be useful for research.

Psychometric Data

Normative data for the GARS-2 were presented by Gilliam (2006). The scale was tested on a sample of 1,107 autistic children and adolescents and compared with scores of children with intellectual disabilities and those without any disabilities. The author reported that the measure successfully screened for autism with the children in the autism group having higher Autism Index (AI) scores than the children in the other groups. A cutoff score of 85 was selected for the AI, and the author reports sensitivity, specificity, and positive predictive values of 0.85 in the intellectual disability group. Reported values were 0.84 for the multiple disability group. The sensitivity of 1.0, specificity of 0.87, and positive

predictive value of 0.85 were reported in the control group.

The author reported internal consistency for the subscales (Cronbach's alpha): Stereotyped Behaviors (0.84), Communication (0.86), Social Interaction (0.88), and 0.94 for the Autism Index. The author reported that concurrent and positive predictive validity had been established (Gilliam 2006).

However, independent studies of the GARS/GARS-2 have not replicated these findings and have expressed concern about the nature of the normative sample and the poor sensitivity of the measure, hence missing a number of children on the spectrum (Lecavalier 2005; Mazefsky and Oswald 2006; Sikora et al. 2008; South et al. 2002). While Eaves et al. (2006) established more positive results for the sensitivity (0.83) and specificity (0.68), these were still significantly lower than the results published by the author. Pandolfi et al. (2010) examined the validity of the GARS-2 and were unable to match the psychometric properties previously described by the GARS' authors.

The authors report good psychometric properties for the GARS-3 (2014) with the measure accurately discriminating autistic children from non-autistic children (sensitivity = 0.97, specificity = 0.97, ROC/AUC = 0.93). Subscale internal consistency reliability coefficients are reported to exceed 0.85 (content sampling), and test-retest reliability coefficients (time sampling) are reported to exceed 0.80 for the subscales and 0.90 for the Autism Indexes (AI). Furthermore, the authors report interrater reliability intraclass coefficients above 0.80 and 0.84 for the AI.

Karren (2017) reviewed the GARS-3 and described improved properties, including the DSM-5-based items and an instructional goals booklet to assist in planning for intervention. The author expresses concern around interpretation of results for the older group (20–22 years) and those from ethnic minority groups. Hence, further data are needed regarding its reliability and validity in broader clinical practice.

Clinical Uses

The GARS-2 is a revision of the GARS and aims to assist in the screening and diagnosis of autism in individuals from the age of 3 years to 22 years. It is a quick and inexpensive means of gathering information from parents, teachers, or caregivers taking between 5 and 10 min to complete. The revised version also aims to provide an indication of severity of the condition and provides the possibility of detecting change over time with respect to discreet behaviors.

There are currently a number of screening measures and rating scales for autism spectrum disorders. These may differ with respect to their focus, strengths, and weaknesses but with the common goal of quantifying autistic features and assisting in the diagnostic process (Lecavalier 2005; Thabtah and Peebles 2019). While some instruments are designed to be administered by a clinician or trained rater, such as the ADI-R (Lord et al. 1994), the ADOS-2 (Lord et al. 2000), and the Childhood Autism Rating Scale (CARS, Schopler et al. 1980), others rely on parental and teacher ratings of behaviors. The ADOS-2 and CARS-2 ratings are also based on direct observations. While widely used in clinics and research, these measures are time intensive for professionals.

Standardized, informant-rated scales, such as the Childhood Autism Spectrum Test (CAST, Scott et al. 2002), the Social Communication Questionnaire (SCQ, Rutter et al. 2003), and the Autism Spectrum Screening Questionnaire (ASSQ, Ehlers and Gillberg 1993), can provide an alternative method of gathering information in an easy and efficient manner. Screening measures also differ with respect to their respective levels. The SCQ, GARS, and GARS-2 are presented as level 2 instruments, i.e., they are used with individuals who are already identified as being at risk for some developmental disabilities and aim to differentiate those with a possible autism spectrum disorder and those with other kinds of

conditions. However, a number of studies have demonstrated concerns about the GARS and GARS-2 with respect to clinical utility owing to psychometric properties.

The GARS and GARS-2 may be useful as a general screening tool rather than a primary tool in the screening and assessment of autism spectrum disorder. The GARS-3 offers more robust information to assist in assessment of ASD but may need further examination regarding its utility in particular groups.

Girls Night Out Model, The

T. Rene Jamison and Jessica Oeth Schuttler
Center for Child Health and Development,
University of Kansas Medical Center,
Kansas City, KS, USA

Definition

Girls Night Out (herein referred to as *GNO*) is a social skills and self-care program designed to address the unique needs of adolescent females with ASD/DD with goals to improve their social-emotional health. GNO is a manualized intervention program that incorporates empirically based strategies and gathers data on program outcomes resulting in a meaningful, socially valid intervention for participants. The program is also unique in that it incorporates typically developing peers as mediators of the strategies, providing socially valid cues and reinforcement for use of skills. Sessions take place in community settings where social and self-care opportunities would naturally occur.

Historical Background

Females with ASD are currently a minority (approximately 25%) of those diagnosed with ASD, and comprise only about 15% of the subjects in published research literature (Watkins et al. 2014). This discrepancy in prevalence is likely related to multiple factors, including an increased genetic risk for males, females with ASD being more likely to be missed, or diagnosed later (Begeer et al. 2013) perhaps because of milder symptom expression (Lai et al. 2015), or because of compensatory skills developed by girls with ASD (Mandy et al. 2012). Researchers and practitioners are beginning to study more closely the unique symptomatology, experiences, and support needs of females with ASD (Lai et al. 2015).

For example, a study examining diagnostic criteria for higher functioning males and females (Hiller et al. 2014) found that not meeting criteria for “restricted or fixated interests...” was predictive of being female. Females were more likely to demonstrate partial impairment in nonverbal skills and no impairment within the “sharing of interests” category as compared to males. If sex differences within the general population suggest females use more nonverbal communication (i.e., eye gaze, gestures), this may explain findings as in Hiller’s study suggesting less or only partial impairment in nonverbal communication.

It is important to note that there are key differences in social interaction and friendship styles between males and females. For example, male friendships tend to be more activity-based, while female relationships include more emotion-focused, empathic connections and relationships (Hannah and Murachver 1999).

As research continues on the unique presentation or symptomatology for females with ASD, relatively little is known about potential differences regarding intervention approaches to promote social-emotional health in females with ASD. The *GNO* program, developed with a basis in empirical approaches, is the first published intervention study specifically targeted to females with ASD (Jamison and Schuttler 2017). The first

author developed *GNO* in 2008 in response to needs identified from clinical experience.

Rationale or Underlying Theory

Rationale

Although females with ASD, particularly high functioning, may demonstrate less impaired social-communication skills at some points in development (Van Wijngaarden-Cremers et al. 2014), they often experience increased social and communication impairments during adolescence as compared to males with ASD (Kirkovski et al. 2013; Koenig and Tsatsanis 2005). Some individuals with ASD demonstrate variable adaptive skills or skills well below the expected performance given their cognitive functioning (Ditterline and Oakland 2009). Thus, for adolescent girls with ASD who have self-care skills below expected norms and limited social interactions, the potential impact on self-perception is significant. Compared to males, typically developing adolescent females demonstrate an increased risk for developing internalizing symptoms such as anxiety and depression (Galambos et al. 2003). The elevated risk for internalizing symptoms and increased complexity in social interaction coupled with social impairment as a core feature in ASD result in adolescent girls with ASD experiencing a “double hit” (Solomon et al. 2012) or “double whammy” (Jamison and Schuttler 2015). In fact, adolescent girls with ASD exhibit significantly more internalizing symptoms (e.g., anxiety, depression) compared to typically developing girls (Jamison and Schuttler 2015) and to boys with ASD (Solomon, et al. 2012), suggesting this is a critical area for intervention. These potential sex differences in social behavior and coexisting social-emotional challenges reflect unique targets within interventions and programs aimed at improving social competence.

Underlying Theory

GNO aims to improve self-perception and self-confidence, anticipating that greater confidence

will result in the increased likelihood of engaging in social “entry” skills and social activities and, in turn, that improved social skills and increased competence will result in improved self-perception and positive social-emotional health. The curriculum targets socially valid behaviors (e.g., reciprocal conversation, shared interests, independence) related to social norms of adolescent females and the unique needs of females with ASD (i.e., improved social emotional competence and emotional health, independence). Instruction and practice occur within age-expected activities, providing a meaningful social experience to individuals who often report limited social opportunities or friendships (Bauminger and Kasari 2000). GNO’s framework is based on social learning theory, behavioral and cognitive-behavioral theories, while embracing concepts related to self-determination, developing social competence, empowering young women, and building inclusive communities.

The theory of change is rooted in Social Learning Theory (SLT) and related behavioral or cognitive-behavioral theories. SLT suggests that people learn new behaviors and/or improve skills through observation (Bandura 1971) and that behaviors are the result of reciprocal interactions between cognitive, behavioral, and environmental determinants. Behavioral theory describes learning skills or behaviors through positive reinforcement and environmental contingencies (Skinner 1988) while in cognitive-behavioral theory, skills are learned by understanding emotional and cognitive interpretations of events, with cognitive and behavioral rehearsal of appropriate behaviors (Kendall 2006).

Our model postulates that behavior changes or skills develop based on some combination of and interaction between observation, practice, and cognitive restructuring that occurs under specific conditions. These conditions include: planned observations for discrete behaviors or skills (live models, video models); repeated exposure and practice across multiple exemplars (skills, people, settings, activities); cognitive restructuring as a result of specific feedback (in vivo coaching and specific praise) and reinforcement of target skills

(differential attention, verbal feedback, token economy); and planned generalization through use of the desired skill within settings future performance is needed. GNO includes similar age girls without ASD/NDD that model skills and use of supports and help to craft opportunities for genuine practice across exemplars, creating frequent, yet natural opportunities to practice target skills. The premise is that experiencing success demonstrating these skills should increase the likelihood of engaging in the behavior in the future, which could be the result of reinforcement principles or cognitive appraisal (e.g., confidence, schema of skill, awareness, etc.), or likely some combination of both. Increased competence or self-perception of competence (confidence) leads to increased engagement in social experiences, which increase social competence and self-perception. While skill increase or enhancement is the immediate goal, a broader intention is to promote independence and positive social-emotional health by improving self-perception and confidence through individually identified goals rooted in the concept of self-determination. Conducting sessions in natural settings and providing training to community-based providers promote communities that are more inclusive.

Goals and Objectives

The goals of *GNO* are primarily twofold: (1) Promote social-emotional health, primarily related to improved social competence, self-perception, self-determination, and perceived quality of life and reduced internalizing symptoms and (2) greater independence and competency in self-care and social skills. Target skills reflect a developmental framework considering expected skills for adolescent females, the unique needs of females with ASD, and individual goals and areas of growth.

Improving Social-Emotional Health

GNO is designed specifically to address common symptoms or challenges females with ASD often encounter, including fewer peer interactions and

social experiences, variable social skills, limited self-confidence, and negative self-perception. By increasing competence and confidence in these social skill areas, the program aims to mitigate symptoms of social anxiety or depression.

Specific objectives related to this goal vary based on individual needs of participants, with core areas related to these broad skillsets: increased frequency and improved quality of conversation entry and reciprocity, more social experiences (e.g., group activities, getting together, phone/text, etc.), setting, monitoring, and achieving goals, and improved self- and caregiver-ratings of social emotional health and competence (self-confidence, self-perception, quality of life, social competence).

Greater Independence and Competency in Self-Care and Social Skills

GNO addresses challenges related to independence completing adaptive behaviors, particularly related to self-care and social skills. Program objectives include fostering greater independence and reducing overreliance on family or other caregivers for self-care and social skills, potentially leading to increases in social supports from peers. The goal is that improved competence within this arena will influence confidence and self-perception, promoting overall social-emotional health. Specific skillsets targeted and measured include: frequency and type of self-care and social activities, and level of independence navigating these activities and tasks.

Treatment Participants

Population

Developed for girls with ASD and other related neurodevelopmental disorders (NDD). Due to the high prevalence of internalizing symptoms in adolescent females with ASD, this intervention targets a broader concept of social-emotional health, and thus appropriate for girls with developmental disability and co-existing mental health disorders or symptoms related to anxiety, depression, and poor self-perception.

Age and Developmental Considerations

Designed for girls *about* 14–19 years old, with positive outcomes found for girls ranging from 8th grade, high school, and a few years past high school graduation (e.g., 18–21 special education program). Girls of a variety of abilities can participate in *GNO* and benefit from the intervention. Previous inclusion criteria for *research participation* required participants to read words at or above a 4th grade level in order to reference printed materials and supports and to demonstrate some conversational speech. However, curriculum and materials are adaptable for individuals of a variety of abilities. Previous adaptations include modified materials (e.g., lower reading level, large print for visual impairments) and inclusion of girls with limited expressive language but capabilities to make some comments contributing to individual or group conversations and receptive abilities necessary to follow directions and comprehend conversation topics and lesson content. Because participants include girls with and without ASD/NDD, groups regularly include girls with a range of cognitive, academic, and communication abilities and various social experiences and interests. The current program description focuses on the adolescent age range, with adaptations currently in progress to modify the curriculum for school-age girls and young adults.

Other Considerations

Independence and choice are valued and thus consent for participation is required from participants as well as caregivers. However, it is not uncommon for participants to express a hesitancy to begin the program and associated social activities. Parents or caregivers are coached at enrollment on how to present details of the program, and acknowledge feelings and concerns of their participant, while also maintaining focus on potential positives of the experience.

Our experience implementing the program over time suggests that frequently, while individuals may not express a desire for friendships or an initial interest in *GNO*, by committing to attending and attempting activities, they are often surprised by the positive effects they experience. These

impacts include increased social interests, desire for ongoing relationships, and positive experiences with the program and fellow participants/peers. Initial enthusiasm of the participant is not essential or predictive of outcomes or engagement in *GNO* activities. Post session survey data indicate high satisfaction regarding program participation for all participants and peer volunteers.

A primary aim in the delivery of this intervention is to tailor supports and strategies to meet the individual goals and needs of each participant, provide social interactions within familiar and unfamiliar activities or settings, promote independence in social and self-care skills, and to facilitate connections (or desire for connections) between girls with similar interests.

Group characteristics might also influence participant outcomes. Enrolment requires parents, peers, and participants to demonstrate availability for nearly all sessions and reliable transportation. Participants are most likely to benefit from this intervention when they attend all (or nearly all) sessions, practice skills, and utilize supports within and outside of weekly sessions.

Treatment Procedures

Program Structure

GNO entails weekly, 2-h sessions over the course of 12–15 weeks. Each session meeting targets one or more of the core curriculum areas and take place during age-typical self-care or leisure activities within community-based settings. Groups include 4–6 participants with a disability (ASD/NDD) and *at least* an equal number of trained peer volunteers. Peer training includes information about peer expectations and activities prior to beginning *GNO* as well as immediately prior to about half or more of subsequent sessions. Each session follows a similar format (see table for *GNO* Session Format), including multiple opportunities to practice targeted self-care or social skills with subsequent sessions designed to build on and reinforce skills from previous sessions. The program utilizes carefully selected empirically based strategies to teach and reinforce skills related to core curriculum concepts.

Targeted social conversation skills are practiced and reinforced in each session and supported by cue cards with tips for conversation (known as “conversation keyrings”), and video modeling clips depicting conversation skills based on the *relating to others* concept. Facilitators utilize differential reinforcement, including specific feedback paired with “*GNO* bucks” (token economy), to reinforce targeted curriculum skills and behaviors tailored to the individual. Participants access support materials housed in personalized *GNO Planners* with homework designed to promote practice and use of skills outside of sessions, including self-monitoring. Participants earn *GNO* bucks for bringing required materials, self-monitoring, and completing homework (Table 1).

GNO Curriculum

The curriculum is organized into three core areas: relationship building skills, promoting independence in self-care skills, and self-determination in social competence and self-perception. The

Girls Night Out Model, The, Table 1 *GNO* Session Format

• Facilitator meeting, preparation, community partner training
• Peer training
• <i>GNO</i> opening activities
- <i>GNO</i> “business” (distribute conversation keyring topics, pay people with <i>GNO</i> bucks for WIDTW sheets, planners, HW)
- Social time (review conversation topics, facilitators provide specific feedback paired with <i>GNO</i> bucks)
• Follow up on homework
• Planned activity or lesson (teach, practice, community partner consult)
• Practice during social or self-care activity with in vivo coaching, specific feedback, and <i>GNO</i> bucks to reinforce target skills
• Data collection
• Closing activities
- Shop at <i>GNO</i> store (token economy)
- Group picture and community partner thank you (if applicable)
- Homework: Assign my <i>GNO</i> friend, review new homework
• Facilitator debriefing
- Integrity checklist, participant notes, next session plans

table summarizes targeted skills within each of these three core areas, with strategies utilized to teach and reinforce these concepts throughout the intervention. (1) *Relationship building skills* address the heightened focus on conversation, relationship building, and shared interests that occur in adolescent female relationships (Hannah and Murachver 1999) and include conversation and friendship skills organized around relating to the person, the activity, and the relationship. Specific social conversation skills serve as “entry” tools to initiate conversation with other girls across contexts and the lifespan, with a focus on both conversation skills (i.e., asking questions/making comments, reciprocal exchanges, complimenting, etc.) and conversation content (i.e., exchange of person-related information, activity or setting related topics, etc.). Concepts to promote “relating to the relationship” include establishing common ground, making plans, and offering encouragement or emotional support. Establishing common ground is obtaining and organizing information about people in your life (personal and shared interests) to create social opportunities and establish relationships. Participants utilize the information about friends or potential friends to guide if, when, and how to initiate making plans and how to identify activities of interest or mechanisms to find social opportunities. Emotional support includes giving and receiving compliments and using verbal and non-verbal encouragers, with ample opportunities to practice and demonstrate these skills during a variety of activities and settings (e.g., fitness, hair salon, ropes course). (2) *Building independence in completing self-care skills* acknowledges difficulties some individuals with ASD experience with daily living skills and addresses the changes in required self-care resulting from biological changes during adolescence. Building independence in self-care skills contributes to improved self-perception and confidence, leading to increased competence in social relationships. The focus within the curriculum is on promoting independence in determining relevant self-care needs and activities, improving skills necessary to complete these tasks, and utilizing supports designed to promote independent use of skills.

Specific areas of focus within the curriculum include selection of clothing consistent with context (setting, weather, activity, etc.); body care (skin, hair); and health (fitness, exercise), tailoring these self-care priorities and activities to align with individual participant values, needs, and interests. Goal development, reinforcement methods, and practice opportunities support skill development while empowering participants to recognize their individual preferences. (3) GNO facilitators *promote self-determination in social competence and self-perception* through specific activities designed to engage participants in guiding their own social-emotional health outcomes. Activities include soliciting information from participants and their families about areas of interest and growth, facilitating individual goal setting and monitoring, and providing opportunities for a shift towards independence and positive peer support. Support targets relate to goal setting, use of visual supports to promote self-sufficiency, and accountability to themselves (self-monitoring, goal revision) and others within their support network (GNO facilitators and participants, caregivers, community partners). Program components include designing strategic opportunities to support the participant’s experience of autonomy, mastery, and control (Ward and Meyer 1999; Wehmeyer 1998) by crafting situations to practice and reinforce specific skills or actions. Community partnerships leverage shared expertise creating rich practice experiences based on knowledge and skills of partner (e.g., hair care and style expertise by salon) and strategies or supports provided by the program (e.g., visual supports for participants and facilitator feedback to community partners). Peer training includes techniques to elicit desired skills from participants or to set the occasion for target behaviors. For example, peers make “bids” in conversation to elicit questions (e.g., “I’m so excited I can hardly wait for this weekend”) and extend pauses before continuing in conversation to allow participants ample time to form questions. Participants receive specific feedback and reinforcement (*GNO bucks*) for use of targeted skills and experience successes within a safe, supportive, and socially valid context. Homework is designed to promote skill use

outside of session, including generalization of skills and goal attainment. Participants earn GNO bucks for self-monitoring and bringing materials to sessions and support fellow GNO participants in goal-related activities or skill practice outside of session as well.

Relating to others	Strategies
Conversation “entry” skills (person and activity topics, giving compliments, asking questions)	Social Learning Theory -peer mediated -video modeling (VM) -Modeling and role play -visual supports (task analysis, my GNO planner, individualized)
Finding common ground	
Making plans	
Emotional support	
Promoting independence in self-care skills	Cognitive and behavioral -reinforce target skills -differential attention -goal setting and monitoring -in-vivo coaching -specific feedback -token economy GNO bucks/GNO store) -planned generalization (natural—/community-based settings, multiple exemplars)
Selecting appropriate clothing	
Body care (hygiene)	
Skin care	
Hair care	
Health (fitness, nutrition)	
Self-determination in social competence and self-perception	
Identify personal strengths and areas of growth (<i>COP M</i>)	
Goal setting and monitoring	
Build self-determination	
Independence in activities/ skills	
Use of supports and technology	

Related Program Elements and Facilitator Roles

Parents or caregivers do not attend sessions with participants. However, a simultaneous *PNO* (*Parents Nigh Out*) component emerged based on experiences conducting groups and feedback from families. *PNO* includes GNO coordinated activities as well as impromptu or parent initiated gathering. Although variable, the goal is for about 50% of sessions to include *PNO* (formal or informal), with a focus on connecting families, sharing resources, and building infrastructure for continued social opportunities and relationships. A parent volunteer from a previous *GNO* group

often coordinates these activities based on feedback from families. Past activities included hosting a guest speaker (e.g., transition specialist), connecting families from current and past groups, or shared resources and support during informal social gatherings. Although *PNO* is optional and not systematically evaluated, families often report benefit from *PNO* events and seem more likely to participate in future *GNO* related activities designed to promote skill maintenance and ongoing social experiences.

An optimal ratio of approximately four facilitators for a group of 9–12 girls is suggested. GNO facilitators utilize a coaching model to give specific feedback about skill use during role-plays and naturalistic practice opportunities for social and self-care skills. Facilitators whisper specific praise or feedback when participants demonstrate target skills or goal-related behaviors. Facilitators utilize principles of differential attention (Pemberton et al. 2013) by focusing attention and feedback on positive behaviors and minimizing feedback about negative or inappropriate behaviors, gradually introducing *some* prompting of skills, still followed by specific praise for exhibiting the skill. Facilitator planning and debriefing provide opportunities for strategic feedback that is tailored to participants and peers based on individual goals and areas of need.

Unique Qualities of Treatment

GNO incorporates unique treatment components along with some common, evidence-based strategies often utilized within social skills programs. One obvious feature is the all-female group designed to address the unique needs of girls with ASD. Although one might argue a 4–5:1 male to female ratio suggests a lesser impact on females as a general population, this discrepancy in diagnosis actually has a residual impact on females with autism, potentially exacerbating social-communication impairments and risk for co-occurring mental health conditions.

The greater representation of males within autism-specific programs and special education services (~66% male; Retrieved 13 December

2017 at https://nces.ed.gov/programs/digest/d16/tables/dt16_204.50.asp) translates to less time girls with ASD spend with similar-aged female peers, narrowing the pool of potential friends and limiting opportunities to practice social interactions and establish relationships with other girls their age. Unlike many social skills programs or settings that target individuals with ASD, *GNO* is an all-female group that provides opportunities for social outings and interactions with other girls about the same age and for families to potentially connect around shared experiences. Families often report few girls in previous social programs, support groups, and classrooms and describe the value of participants and families connecting and relating to one another. Use of a coaching model, with peer-mediated strategies for teaching and practicing skills, provides authentic and genuine opportunities for practice within realistic social settings. The model and curriculum reaches beyond skill building and targets overall social-emotional health. Partnerships within the community promote shared expertise between local professionals and facilitators with disability-specific expertise and work towards more inclusive communities.

Efficacy Information

Clinical outcome data, based on a combined sample ($n = 34$) from five groups across the past 4 years, suggests *GNO* is desirable to families and shows promising results for improved conversation and social-emotional outcomes in adolescent girls with ASD (Jamison and Schuttler 2017). Sample sizes for outcome measures vary ($n = 14$ – 34) as evaluation procedures evolved over time. Results show statistically significant improvements following intervention for total social competence ($p = 0.035$, $ES = 0.53$) and related subscales, global self-perception ($p = 0.008$; $ES = 0.53$), and Quality of life ($p = 0.04$, $ES = 0.52$). Participants also reported a significant decrease in internalizing symptoms ($p = 0.04$, $ES = 0.47$). Although samples are small,

medium to large effect sizes suggest meaningful improvements. Consumer satisfaction ($n = 36$) is high (*satisfaction with program activities* = $4.5/5.0$; *positive changes in specific skills* = $3.5/5.0$) with ratings from parents, participants, and peers signifying the intervention is a service that families value and need.

Program activities and targets skills reflect an iterative process informed by the literature and ongoing involvement of participants, peers, and families. Program *activities* arose initially in part from group discussions with typically developing, adolescent females between the ages of 13–18 years old ($n = 10$; Caucasian and living in a suburban community in a large Midwestern city in 2008). Subsequent activities and target skills reflect feedback from previous groups and our research on girls with ASD. Examining factors that influence peer acceptance revealed *engagement* as a critical component in successful conversations (i.e., asking questions, looking and sounding interested, nonverbal encouragers; Jamison et al., poster presented at AUCD 2012), which informed and validated the core components of relationship building skills. Preliminary findings from our qualitative study (Schuttler, Jamison, & Edwards, poster presented at IMFAR 2014) provide evidence for the theoretical framework and curriculum components that foster independence and promote reliance on positive peer influence rather than adults. Typically developing females ($n = 46$; mean age = 16.4) reported increased social complexity, greater independence, and more reliance on peers compared to family; however, girls with ASD ($n = 14$; mean age = 15.57) relied significantly more on family members (e.g., parents) for social and self-care support.

Outcome Measurement

The program uses informal and formal methods of measurement for key outcome areas of social skills/competence, self-care/adaptive skills, self-perceptions, and social-emotional functioning (including both broad quality of life and more

specific internalizing/externalizing symptomatology). Current tools used for pre-, post-, and follow-up measurement of key skill areas include the Behavior Assessment System for Children, 3rd Edition (BASC-3), Parent and Self Report, the Social Skills Improvement System (SSIS), Social Responsiveness Scale-Second Edition (SRS-2), Self-Perception Profile for Adolescents, 2nd Edition (SPPA-2), Autism Social Skills Profile, Youth Quality of Life (research version), and a self-care checklist developed concurrent with the program. Interview and ratings using the Canadian Occupational Performance Measure (COPM) inform goal development and attainment.

Data is collected throughout the session for some skills. Participants and peers self-monitoring specific skills related to social competence, adaptive skills (self-care, hygiene), and individual goals throughout the session. A few previous groups included evaluation of specific conversation skills as part a research study using a conversation coding system. Satisfaction data is collected at the conclusion of the program from peers, participants, and parents using Likert scale ratings of activities and skill levels and as an opportunity for families to provide written feedback about their experience.

Qualifications of Treatment Providers

Sessions typically involve two kinds of facilitators: lead and support. The lead facilitator is responsible for guiding the session and supervising overall session activities. Support facilitators help with setup and follow up post session. Both types of facilitators are responsible for in vivo coaching and feedback, teaching and supporting skills within session. The lead facilitator (1) should have background in implementing social skills programming and have experience with individuals with developmental disabilities. Support facilitators (2–3) usually have at least a bachelor's degree related to education, behavioral sciences, psychology, or communication sciences. Experience with individuals with ASD and other

DD is very helpful. For more information on individualized training for local implementation of the program, readers are encouraged to contact the authors of this chapter.

Glasgow Sensory Questionnaire (GSQ)

Ashley E. Robertson¹ and David R. Simmons²

¹School of Psychological, Social and Behavioural Sciences, Faculty of Health and Life Sciences, Coventry University, Coventry, UK

²School of Psychology, University of Glasgow, Glasgow, UK

Synonyms

Adult/Adolescent Sensory Profile (AASP); Inventory of Interpersonal Situations (IIS); Principal component analysis (PCA); Sensory Sensitivity Questionnaire (SSQ)

Description

The Glasgow Sensory Questionnaire is a 42-item measure, which captures self-rated hyper- and hypo-sensory sensitivity to stimuli across seven sensory domains (Robertson and Simmons 2013). It was initially constructed based on reports of common sensory signs and symptoms associated with ASD. The sensory domains represented in the measure are visual, auditory, gustatory, olfactory, tactile, vestibular, and proprioception. Items are equally distributed among sensory modalities, with three questions assessing reported hypersensitivity and three determining hyposensitivity. All questions ask how frequently certain sensory events were experienced, with participants responding using the scale: “Never–Rarely–Sometimes–Often–Always.” Responses are coded on a scale from 0 to 4, with possible scores ranging from 0 to 168.

Questions are phrased to ask if participants currently encounter the sensory events described. However, if the frequency with which they experience such events has changed over their lifetime, they are asked to choose the response that best matches their experiences over the preceding 12 months. Sample questions are included at the

start of the questionnaire in order to highlight these points.

The questionnaire has been translated into six languages, with the French (Sapey-Triomphe et al. 2018), Japanese (Takayama et al. 2014), and Dutch (Kuiper et al. 2019) versions being published thus far. Our key results have been replicated in a larger sample (e.g., Horder et al. 2014). The GSQ is a useful measure of sensory processing beyond autism and has, for example, been used by researchers exploring synesthesia (Ward et al. 2017, *Scientific Reports*) and traits in ADHD (Panagiotidi et al. 2018). Informal reports by users of the GSQ for research purposes suggest that this questionnaire provides a quick and useful characterization of sensory sensitivities in both autistic people and non-autistic individuals.

The original GSQ was designed as a self-report questionnaire for adults, but recently efforts have been made to validate a caregiver report version (Smees et al. 2019) and a self-report version for children (Simmons et al. 2016; Millington and Simmons 2019).

In addition to replications of the original study in different populations and cultures, the GSQ has come to be used as a useful instrument for characterizing sensory sensitivities in empirical studies, especially when the experiment has a sensory component, for example, Freyberg et al. (2015) and Poole et al. (2017), in their comparisons of binocular rivalry and temporal order judgments, respectively, between autistic and control groups.

Historical Background

The Glasgow Sensory Questionnaire was initially developed with 70 items (version 1.0); this was subsequently reduced to 42 items after a principal component analysis (PCA) (version 1.1). This is reported in Robertson and Simmons (2013). The reduction affected all modalities equally (the number of items for each modality was reduced from 10 to 6, with an even split between questions targeting hypersensitivity and hyposensitivity). Version 1.2 was released in 2018, correcting an error that existed in the coding sheet.

Psychometric Data

In the original study (Robertson and Simmons 2013), reliability analyses for the 42 items of the questionnaire were reported: Cronbach's alpha (0.935) and Guttman's split-half technique (0.929). These scores indicated acceptable levels of reliability. Principal component analysis was used to reduce the number of items from 70 to 42 and also explore the factor structure, with a single underlying factor being identified.

Ujie and Wakabayashi (2015) reported psychometric features of the Japanese version of the GSQ. Internal consistency using Cronbach's alpha was acceptable (0.84). A joint factor analysis of the GSQ and AQ showed a two-factor solution, with the GSQ loading onto the first factor and AQ (minus the "attention to detail" subscale) loading onto the second factor. The authors highlighted that there are some differences in performance between high and low AQ scorers, something that warrants further analysis.

Sapey-Triomphe et al. (2018) conducted a comprehensive psychometric analysis of the French version of the GSQ, comparing to the original version (Robertson and Simmons 2013). They found that the GSQ score was very similar between the two studies, with all but one of the items in the French version (number 39) being within 1 standard deviation of the original English version. Internal consistency was assessed using Cronbach's alpha (0.95 for all 42 items; 0.94 for 14 subscales). They used factor analysis to assess the GSQ and found evidence of two factors, one consisting mainly of hypersensitive items and the second of hyposensitive items. This was observed in both high AQ and low AQ groups, but there were some fine-grain differences between the groups (e.g., more variance was explained for the high AQ group than the low AQ group).

Kuiper et al. (2019) investigated the psychometrics of the Dutch version of the GSQ, comparing those with a diagnosis on the autistic spectrum and those without. They reported excellent levels of reliability in both groups (autistic, 0.91; non-autistic, 0.90) for the whole questionnaire and good levels for the hyper (autistic, 0.87;

non-autistic, 0.85)- and hyporesponsiveness (autistic, 0.85; non-autistic, 0.81) scales. Reliabilities for the individual modalities were mixed. Test-retest reliability was high for both groups (autistic, $r = 0.92$, $p < 0.001$; non-autistic, $r = 0.83$, $p < 0.001$). Convergent and divergent validity was also assessed, by comparing data from the GSQ to (a) established self-report measures of sensory responsiveness and (b) non-sensory measures, for example, those measuring social skills. To measure convergent validity, the Dutch version of the GSQ was compared to the Adolescent/Adult Sensory Profile (AASP; Brown and Dunn 2002) and Sensory Sensitivity Questionnaire (SSQ; Minshew and Hobson 2008). Between the GSQ and AASP, a strong correlation was reported for the autistic group ($r = 0.77$, $p < 0.001$), with a moderate correlation for the non-autistic group ($r = 0.66$, $p < 0.001$). A moderate correlation was observed when compared to the SSQ (autistic, $r = 0.51$, $p < 0.001$; non-autistic, $r = 0.56$, $p < 0.001$). To assess divergent validity, the GSQ was compared to the Inventory of Interpersonal Situations (IIS; Van Dam-Baggen and Kraaimaat 1999). A small nonsignificant correlation existed for the autistic group ($r = 0.03$, $p = 0.78$) and a small negative correlation with the non-autistic group ($r = 0.25$, $p = 0.04$).

Clinical Uses

At this time, widespread clinical use is not recommended since further validation studies are needed. However, clinicians have obtained the GSQ for using in a clinical setting. The main purpose is reportedly to help identify areas of sensory need. It is important to highlight that diagnostic or eligibility decisions should not be based upon GSQ scores. However, on a case-by-case basis, the GSQ might help indicate which individuals need more extensive evaluation and perhaps offer some ideas about intervention. Professionals experienced in treating sensory processing problems in adults with ASD or related conditions should contact the authors before using the GSQ to discuss its appropriateness.

Global and Regional Asperger Syndrome Partnership (GRASP)

Kate Palmer
GRASP, New York, NY, USA

“Global and Regional Asperger Syndrome Partnership (GRASP)” was created by a group of individuals with Asperger’s syndrome in New York City seeking to form an organization run by people with Asperger’s and autism spectrum disorder in order to help their peers. In 2003, GRASP was gifted a generous grant by the FAR fund and subsequently filed for 501c-3 status to become a nonprofit. Since then, the GRASP team has expanded the organization to include more programming specific to increasing the independence of autistics and individuals with autism spectrum disorder. GRASP’s team has established structured workshops, social events and groups, as well as increasing the visibility of ASD adults within society through collaborative work with high-profile regional, national, and international organizations.

GRASP’s mission is to improve and enrich the quality of life of autistic teens and adults and individuals on the autism spectrum and their

families through community advocacy and outreach, education, peer supports, programming and services, at no cost to our members.

GRASP’s vision is to actualize and work toward a world where all autistic individuals and individuals on the autism spectrum are self-determined, respected, valued, and fairly represented, where appropriate supports and services are readily available to those in need, where people on the spectrum are empowered to participate in personal decisions that affect their lives and to achieve their dreams.

With over 20,000 members – over 40 in-person groups, online support groups, and real-time chats with GRASP staff, and information and referral services for individuals and families – GRASP is the largest organization for individuals with ASD. GRASP has a strong presence on social media through Facebook, Twitter, LinkedIn, and through website information and support.

For more information, visit www.grasp.org or contact by email at info@grasp.org.

Global Aphasia

Elizabeth R. Eernisse
Department of Language and Literacy, Cardinal Stritch University, Milwaukee, WI, USA

Synonyms

[Dysphasia](#)

Definition

Global aphasia is a disorder of language characterized by a severe impairment in all aspects of spoken and written language across comprehension and production.

When considering types and categories that fall under the broader term “aphasia,” global aphasia is among the most severe of the nonfluent aphasias as both comprehension and production of language are involved.

Estimates of global aphasia in the larger population are largely unknown, though it has been estimated that 80,000 people develop aphasia in the United States each year.

The prognosis for individuals with global aphasia is largely dependent upon the extent of the damage to the brain and the severity of the impairments they encounter. For some individuals, an initial global aphasia resolves as swelling in the brain decreases and the patient is left with residual symptoms that are more consistent with Broca's or Wernicke's aphasia. For others, the impairments across comprehension and production persist. Factors including age of onset, health, education level, and how soon treatment takes place after brain damage have been shown to be predictive of recovery in aphasia.

Individuals with global aphasia have often experienced significant damage to the majority of the "language centers" of the brain, including the arcuate fasciculus, Broca's area, and Wernicke's areas of the left hemisphere. Language skills are typically impaired across comprehension and production, and individuals are often rendered without functional speech or produce repetitive/rote speech only.

Intervention for individuals with global aphasia largely depends on the severity of the symptoms experienced. As both comprehension and production are impaired, treatment often focuses on providing the individual with maximal support and compensatory strategies. In addition, family and caregiver training and supports are critical to the recovery and management of global aphasia.

Definition

Local and global processing refer to hierarchical dimensions within perceptual patterns. Any spatially or temporally extended structure can be dichotomized in its embedding component or global level, and its embedded components or

local elements. Local and global dimensions are interdefined and are therefore only relative concepts: the same level can be considered as local relatively to its embedding structure and as global if it can itself be decomposed into embedded elements. The classic local–global tasks use “Navon-type” stimuli, which are large patterns (e.g., letters, geometrical figures) composed of small patterns of same or different nature (see Fig. 1). In the auditory modality, hierarchical stimuli can be implemented in melodies where local elements are single pitches or intervals, and global elements are melody or contour.

Global level has to be distinguished from holistic level, which is a pattern emerging only from the combination of local and global elements. For example, in a face, global level would be the face outline, parts would be eyes or mouth, but holistic (or gestalt) level would be the information that it is a face, which emerges only from the integration of parts and whole together. Whereas local versus global terminology is technically related to laboratory studies of pattern construction, whole and parts are akin to the gestalt tradition and refer, when empirically studied, to the relation between perception and understanding/recognition processes.

Differences in priority, speed, and accuracy of access to global versus local level information

Global Versus Local Processing, Fig. 1 Navon-type stimulus

define global or local *advantage*. The facilitating or detrimental effect that the processing of one level has on processing of the other is called *interference*. For example, dissimilarity between local and global level has typically more detrimental effect on the local than on the global processing: global-to-local interference is usually larger than local-to-global interference. Combined global advantage and superior global-to-local interference is called global *precedence* in cognitive literature (Robertson and Lamb 1991). The term *precedence* is usually replaced by *bias* in the autism literature.

Local and global levels differ not only in their logical and spatial relationships or hierarchical status but also in their respective psychophysical dimensions, neural representation, and relation with further recognition and labeling processes. For visually presented information, spatial frequencies are the average number of elements per unit of length. Global level is therefore composed of lower spatial frequencies and local level of higher spatial frequencies. In terms of neural representation, the local–global distinction is represented within the feed-forward flow of information of visual processing, in the form of a smaller versus larger amount of cells required to code the information (Grill-Spector and Malach 2004). Local elements require the integration of multiple psychophysical dimensions (contrast, luminance, and color). Local processing level is therefore anatomically and functionally more akin to low-level perception, level at which orientation or luminance discontinuities are coded. Conversely, global elements are anatomically and functionally closer to further levels of processing, as object recognition and labeling require the construction of a global representation (Grill-Spector and Malach 2004). Emotional value, for example, is mostly conveyed by global aspects of socially relevant material (Pourtois et al. 2005).

Historical Background

The local–global issue in autism goes back to Kanner’s initial description of various autistic behaviors apparently related to “irrelevant” or

“minute” aspects of their surroundings. Kanner’s first writings emphasized a dependence of the access to global dimension of an object or situation on *integrity* of all its parts. Thus, autistics would present an “inability to experience wholes *without full attention to the constituent parts*.” Kanner therefore did not postulate a *deficit* in the perception of global aspects of objects, but rather a *mandatory consideration of details* in the recognition/manipulation of entire objects or situations. Kanner’s reference to a perceptual hyperaccuracy and to superior performance of perceptual memory, “photographic or phonographic identity,” was explicit in this context (Kanner 1951). The detail-whole distinction, which may be considered as the ancestor of the “local–global” distinction in autism, had initially two meanings, which, although conceptually and ecologically interconnected, should be distinguished. First, *details* are opposed to *entire objects* and refer to a hierarchical relation of inclusion between levels within a perceptual pattern. This relation occurs within perception: local and global aspects are both perceptual features. This interpretation will be referred to as the within-perception meaning of the local–global distinction. Second, details refer to the entire domain of phenomenal appearance or perception, and whole refers to meaning, function, or use of a perceptually distinct pattern or object. In this latter case, “attention to details” refers to an atypical top-down relationship between perception and other elements of cognitive architecture involving higher-order processes. This constitutes the top-down meaning of the local–global distinction. Both meanings are contained in Kanner’s statements on the relation between sameness and detail, in that sameness is the preservation of detailed perceptual appearance of the world, as opposed to its meaning or function. In contrast, the default level of conscious cognitive functioning in typical individuals is that of meaning, which bypasses the detailed appearance (Kanner 1951). The ambiguity between a within-perception and a top-down approach of local–global issues in autistic perception has obscured empirical research on perception in autism for 50 years.

After Kanner, the top-down approach was the first to be developed. Creak (1963) described in autism an interest for object characteristics independently of their function. Hermelin and O’Connor (1970) expanded the idea that autistics have access to “raw processing” which, according to the dichotomy in use at that time, corresponds to the idea of uncategorized, perceptual material. The top-down approach is also the basis for the weak central coherence model, which emerged during the late 1960s and 1970s through studies from Hermelin’s student, Uta Frith, before its first formal description in 1989. In one of her landmark papers, Frith opposed *gestalt* to *perceptual detail* and to *raw material* (Shah and Frith 1983). The Embedded Figures Test used in this paper, which contains two embedded perceptual levels, bridges the top-down to the within-perception interpretations, though it was not exploited as such. The enhanced detection of embedded figures was attributed to autistics being “less captured by meaning.” The gestalt was not clearly considered as a perceptual impairment in autism since autistics could label global pictures.

The local–global conceptual distinction appears in these terms in 1993, simultaneously in Shah and Frith’s study on Block Design task, with a mostly top-down approach, and in Mottron and Belleville (1993) with a strictly perceptual approach. For Shah and Frith, “a relative preference for processing local as opposed to global features” is attributed to a deficit in global processing, understood in a top-down sense. Therefore, the hypothesized deficit is not primarily perceptual, but refers to diminished or absent top-down influence on the entire field of perception. Tasks used to support these assumptions were also not primarily perceptual (they involved response times of several tens of seconds) despite presenting a hierarchical component. In contrast, Mottron and Belleville (1993) investigated hierarchical effects within perception with the description of perceptual analysis in an autistic savant draftsman, with a mixture of strictly perceptual (hierarchical stimuli, perception of impossible figures) and visuoconstructive tasks (graphic construction). They reported that the hierarchical processing and graphic construction of visual

representation did not present the global precedence effects evident in typical individuals.

In the following years, this ambiguity remained, resulting in two partly overlapping, partly antagonist trends of research: one on perceptual laws, the enhanced perceptual functioning model, with a late incursion in top-down influence on perception; the other on top-down effects or weak central coherence, with a late incursion in perceptual laws. Both are unfortunately confounded in the “local–global” issue. Consequently, the question “is there a global deficit” and “is there a local bias” in autism received two empirically and theoretical answers, according to the within-perception or top-down approach of these terms. The cliché contrasting enhanced perceptual functioning and weak central coherence models, with the first emphasizing intact global processing and the other supporting impaired global processing, is misleading. The term global has a within-perception meaning in the enhanced perceptual functioning model and a mainly top-down meaning in the weak central coherence account.

Current Knowledge

Only the within-perception meaning of the local–global distinction will be presented here. Visual perceptual hierarchy has been studied in autism through perceptual hierarchical tasks, in which response times are in the range of hundreds of milliseconds, thereby more prone to tap specifically perceptual processes, and visuospatial hierarchical tasks, in which the answer requires several tens of seconds.

Perceptual hierarchical tasks include Navon-type hierarchical stimuli, part-whole relationships in patterns and faces, and attentional search tasks. A review by Wang et al. (2007) of nine studies using hierarchical stimuli in autism, for a total of 96 autistic spectrum individuals and 126 typical individuals, reveals that group differences, when found, involve superior local bias or local-to-global interference in autistics. Response times

to global level stimuli among autistics are more affected by incongruent stimuli at the local level than are the response times of typical individuals. The default setting of hierarchical autistic perception can also be assessed by prompting the participant to the likelihood of the occurrence of the stimulus at one level or the other. Autistics present a shorter response time for local element similarity than for global similarity, contrary to typical individuals, with equivalent accuracy in both groups. Another consistent result in this type of tasks is autistics’ typical performance level for various aspects of multi-features, global pattern dimensions when constrained to do so (except in specific cases that cannot be considered as representative of the autistic population). Typical holistic processing is manifested by standard effect of “good form” on visual target detection; typical global advantage under various visual angles; faster response to global as compared to local configurations; similar influence of structural global bias, although to a lesser extent than typically developing individuals; and slower response to local stimuli in global incongruence condition or global interference (see Happe and Frith 2006; Mottron et al. 2006, for reviews). A neighboring approach of the local–global distinction is represented by attentional visual search tasks, in which the participant has to disembody targets from surrounding task-irrelevant distracters which share one or several features with the targets. Autistics usually display faster target detection, more accurate discrimination of elementary stimuli differing at the feature level, and diminished influence of increasing number of distracters (Plaisted et al. 1998). For social material (e.g., faces), autistics display a preference for local information in identity matching, a superior priming effect of face parts, and a generally superior processing of high spatial frequencies in tasks involving faces. Integrity of global level analysis is demonstrated by typical gains from the addition of configural information, mostly typical inversion effect, and by superior recognition of an embedded facial target compared to an isolated one.

Visuospatial hierarchical tasks in the autism literature comprise mainly the Block Design subtest of the Wechsler scales of intelligence, graphic reproduction of possible and impossible figures, and the Embedded Figures Test. Autistics display a constant pattern of enhanced performance in these tasks. When the processing of a global aspect conflicts with a local analysis among typical individuals (e.g., perceptual cohesiveness in Block Design, impossibility of a figure in graphic reproduction, and visual context in embedded figures), autistics perform better than typical individuals. In contrast, when this conflict is diminished, for example, by segmentation to diminish the perceptual cohesiveness in Block Design or by copying possible instead of impossible figures, autistics are brought back to a level of performance equivalent to that of typical individuals. Conversely, autistics are not rigidly bound to a local strategy, as demonstrated by their capacity to switch to a global strategy when required by the task (Caron et al. 2006).

Analogues of Navon-type stimuli in the auditory modality allow investigating hierarchical effects in auditory modality, by using the single note versus melody or chord perception, with the same message of enhanced perception of local elements and intact perception of global auditory patterns, despite diminished detrimental effects of pitch and timing interference on judgments of pitch change. Even when considered in isolation, some psychophysical properties of auditory elements such as pitch are processed more accurately in autistics (Bonnell et al. 2010). The same applies to visual modality, in that lower thresholds for luminance-defined features are reported in autistics (Bertone et al. 2005).

Main Accounts

Despite the apparent homogeneity of autistic “local bias,” the large array of tasks grouped under the umbrella term of local–global tasks renders poorly plausible the notion of a unitary mechanism. Explanations are centered either on

the modification of within-perception hierarchy under the constraint of altered processing of elementary visual and auditory properties or on the modification of top-down influences on perception.

Within-perception accounts: Visual and auditory hierarchical tasks share the requirement to detect, identify, match, or reproduce a local target embedded in a larger probe. The enhanced perceptual functioning model proposes that an intrinsic superiority in pattern detection may have the effect of a local bias in comparison to typical individuals. This superiority can be traced back to an enhanced processing performance for the psychophysical properties of the patterns for which autistics display superiority. This is well demonstrated in the auditory modality (superior pitch perception), with some correspondent in the visual modality (enhanced perception of luminance-defined gratings) or in intermodal perception (enhanced perception of audiovisual synchrony). In some tasks like melody and verbal pattern discrimination, visual search, block design, and face perception, the local bias can be directly related to enhanced feed-forward processing of elementary psychophysical visual features. In support of this account, the same autistics who display the higher level of “local bias” also display superiority in low-level discrimination tasks as well as in a wide range of pattern identification tasks (Caron et al. 2006). Conversely, a multimodal local bias may be involved in atypical perception of social releasers. For example, the preference for high-spatial frequencies may modify face scanning as well as the route of emotion interpretation, as most of the emotional aspects of faces are conveyed by low spatial frequencies (Vlamings et al. 2010).

Top-down accounts: Another series of accounts attributes the local bias, evident in autistics, to a diminished global precedence within hierarchical patterns. The type of limitation of a top-down intervention favoring global over local processing varies according to accounts. The weak central coherence account, initially proposed for the Embedded Figures Test and the

Block Design task, hypothesizes a deficit in the typical tendency to favor a gestalt approach. For example, increasing the perceptual cohesiveness of the figure to be reproduced double the execution time in typical individuals, without influencing response times in autistics with a Block Design peak. The concomitant superiority of these autistics in a *global* task discounts the possibility that their remarkable performance on the Block Design task derived from a deficit in analyzing global aspects of a figure (Caron et al. 2006). Within the enhanced perceptual functioning account, M. Dawson's optionality model states that autistics are not obligated to use a global strategy when a global approach to the task is detrimental to performance (Soulières et al. 2007). For example, autistic persons are better able than typically developing persons to copy globally impossible figures, but as able to identify that these figures are impossible. Optionality may apply both to the competition between local and global level within pattern construction and between meaningless and meaningful processing of perceptual material.

Conclusion

Two findings clearly emerge from the now extensive investigation of local–global processing in autism. First, when the processing of the global aspect conflicts with a local analysis among typically developing persons, autistics either display superiority in local detection or present a diminished influence from the global level on the local one. Second, when the global level is tested in isolation, it is unremarkable; when the local level is tested in isolation, it is either unremarkable or superior. When it can be disentangled from other executive, intentional or motor components, the active ingredient in autistics' atypical performance is invariably of a perceptual nature. Local bias has two sources: an altered low-level input shared by most perceptual tasks in which autistics display superiority, and a diminished influence on local processing from either global perceptual

channel or top-down, nonperceptual processes. These findings appear consistent across visual and auditory modalities, for short as well as long exposure tasks. Local bias in autism is now consensual and represents one of the strongest arguments for an atypical perception in autism as well as a key path to the understanding of overall autistic cognition.

Future Directions

- Which low-level property is responsible of enhanced pattern detection, when observed?
- Are elementary grouping processes intact, atypical, or impaired?
- Lateral interaction and crowding as possible contour enhancers
- Role of altered spatial frequencies in face perception
- Role of pitch processing in language acquisition
- How do hierarchical atypicalities cluster in the same individuals?

Globus Pallidus

Wouter Staal

Neuroscience, Radboud University Nijmegen
Medical Centre Karakter, Nijmegen,
The Netherlands

Synonyms

Paleostriatum

Definition

Its name derived from the Latin for “pale globe” and also termed the paleostriatum the globus pallidus (GP) is a subcortical structure of the brain and part of the basal ganglia. For some time it was associated with the putamen and referred to as the lentiform nucleus. Topographically, the globus pallidus it is part of the telencephalon and a major component of the extrapyramidal motor system. It connects with the substantia nigra, which is quite similar in neuronal architecture. The GP is divided into two parts – termed the internal and external GP – by the medial medullary lamina. These nuclei receive GABAergic axonal terminal branches from the striatum. Damage to the GP may result in stereotyped behavior and impaired extrapyramidal motor functioning. The GP is a target for deep brain stimulation therapy in Parkinson's disease.

Glu

► Glutamate

Glutamate

Eunice Yuen

Yale Child Study Center, New Haven, CT, USA

Synonyms

Glu; Glutamatergic

Definition

Glutamate (Glu) is a neurotransmitter that governs the excitatory synaptic transmission in the central nervous system. It plays a key role in brain development, such as migration, differentiation, survival, synaptic pruning, and plasticity. Glu activates ionotropic receptors including α -amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid receptor (AMPA) and N-methyl-D-aspartate receptor (NMDAR), as well as metabotropic glutamate receptors (mGluR 1-7). Aberrant Glu system has been implicated in autism spectrum disorder (ASD). ASD patients show elevated serum levels of Glu, and increased brain expression of glutamate receptor and transporters. Increased densities of dendritic spine, a specialized compartment of glutamatergic synapse, correlate with decreased brain weight and severity of ASD symptomatology. In ASD-like animal models, abnormal pre-synaptic glutamate release, glutamate-mediated neurotransmission, and plasticity are found, and dysfunction of glutamate transporter leads to overproduction of glutamate and NMDAR-mediated excitotoxicity. At the genetic level, missense mutations of genes encoding Glu receptor are found in ASD patients,

while animals expressing these mutated genes show abnormal Glu channel properties and glutamatergic synapse morphology. Clinically, both agonists and antagonists of NMDAR have been reported to ameliorate ASD-related symptoms in human, suggesting that deviation of NMDAR activity in either direction may be implicated in ASD. Most significantly, alteration of glutamate synaptic transmission may lead to excitation-inhibition imbalance within the neuronal network, which has been postulated as pathophysiology of ASD.

Gluten-Free Diet

Susan Hyman

Developmental and Behavioral Pediatrics,
Division Chief Neurodevelopmental and
Behavioral Pediatrics, University of Rochester
Golisano Children's Hospital, Rochester,
NY, USA

Definition

The gluten-free and casein-free diet (GFCF diet) is a popular dietary intervention used by families of people with autism spectrum disorders (ASD) in the effort to lessen core symptoms of ASD and/or gastrointestinal problems like bloating, diarrhea, and discomfort that may impact behavior. Gluten is a peptide (protein) found in grains such as barley, rye, and wheat, which provides elasticity to baked goods. Casein is a peptide found in all milk and milk products. The GFCF diet eliminates grain and dairy foods containing these peptides and processed food products containing them. Current use of a diet eliminating gluten and/or casein is reported by less than 20% of families participating in the Autism Treatment Network (Perrin et al. 2012).

Historical Background

Elimination diets have been investigated as means of altering behavior in people with developmental, behavioral, and medical diagnoses for many years. Case reports in the 1970s described individuals with symptoms of ASD whose behaviors improved with elimination of multiple foods including wheat products (Bird et al. 1977; O'Banion et al. 1978). In the 1970s and 1980s, the potential for dietary intervention to impact attention and hyperactivity was studied in clinical trials with largely negative results in the USA (see ► [Feingold Diet](#)). During this period, investigators in the UK and Norway observed that some

individuals with symptoms of ASD or schizophrenia seemed to improve with elimination of gluten and casein from their diets (Milward et al. 2008). To explain this clinical observation, they examined urinary excretion of peptides (proteins) that they thought were related to these foods. The GFCF diet gained popularity in the late 1990s through anecdotal reports of success, books for families in the popular press (Lewis 1998), and web-based organizations that supported families in implementing the GFCF diet.

Rationale or Underlying Theory

To explain the observation that some people with ASD seemed to have improvement in behavior or medical symptoms with elimination of gluten and/or casein, Shattock et al. (1990) and Reichelt et al. (1991) suggested the hypothesis that people with ASD had a "leaky" intestinal lining that allowed proteins to be absorbed from food that typically were not absorbed and that these substances subsequently acted like opiates in the brain. An additional hypothesis has been proposed that increased absorption of peptides related to casein and gluten may be due to altered gut peptidase activity (Christison and Ivany 2006).

Urine peptide measurement in people with autism on and off GFCF diets was published that suggested an increase in urine metabolites of gluten and casein that could be decreased with dietary intervention (reviewed in Christison and Ivany 2006). Measurement techniques for urinary peptide identification were less precise in the 1980s, so the compounds separated in the urine could not be specifically identified. Subsequent studies using newer and more accurate measurement techniques did not identify increased excretion of opiate-like peptides related to gluten and casein in children with ASD compared to controls (Cass et al. 2008; Hunter et al. 2003).

Although the original "opiate hypothesis" has not been supported by the more recent studies of urine peptides or current understanding of the neurobiology of ASD, it is plausible that the

empiric observation of behavioral improvement with dietary restriction may have an alternative explanation in subgroups of children with ASD. Celiac disease is an autoimmune disorder found in up to 1% of the population. Antibodies to gluten alter the intestinal lining in response to gluten exposure. This results in characteristic findings on blood testing for antibodies and on biopsy of the intestine performed during diagnostic endoscopy. Elimination of gluten from the diet in people with celiac disease results in improvement in gastrointestinal symptoms (e.g., pain, diarrhea) that might lead to irritability. Neurological symptoms associated with celiac disease include ataxia and peripheral neuropathy with anecdotal reports of impaired attention. Other hypotheses have been proposed regarding primary immunologic abnormalities in the intestine in people with ASD (Buie et al. 2010). Another potential explanation for improvement in behavioral symptoms in a subgroup of children with ASD is lactose intolerance. Lactose is an enzyme that allows the intestine to break down milk sugars found in cow's milk. The genetic predisposition to lactose intolerance is especially common in certain ethnic groups. Lactose intolerance may also occur after gastrointestinal infections from viruses or bacteria. If someone is lactose intolerant, elimination of milk sugar might decrease irritability from bloating and decrease diarrhea. Some people might benefit from an elimination diet if true allergy or dietary intolerance to milk protein or other foods. The most common food allergies include milk, wheat, eggs, tree nuts, and soy. It is also plausible that the elimination of processed foods containing gluten and casein changes the diet in other ways such as removal of food dyes and preservatives (see ► [Feingold Diet](#)). Alteration of the foods eaten may change the microbial environment in the gut which could potentially alter absorption of nutrients that are precursors to neurotransmitters (Dinan and Cryan 2017).

Goals and Objectives

The GFCF diet is typically trialed by families to determine if the symptoms of ASD or of gastrointestinal distress can be lessened with total

elimination of casein- and gluten-containing foods. Clinical studies to date have attempted to examine outcome criteria related to the core symptoms of ASD, language, and nutritional status.

Treatment Participants

The published studies in the scientific literature have used different criteria for characterizing the participants, controlling for behavioral and medical interventions that might impact change in symptoms over time, age of participants, the rigor with which the diet was monitored, and medical conditions which might impact outcome. Several case series (reviewed in Christison and Ivany 2006; Mulloy et al. 2010; Millward et al. 2009) and a single-blind study (Knivsberg et al. 2002) report on children with clinical diagnoses of ASD. The children in these studies ranged in age from 3 to 17 years. No attempt was made to control for other interventions. A larger single-blind trial (Whitely et al. 2010) reported on children whose diagnosis of ASD was supported by the Autism Diagnostic Observation Schedule. A smaller double-blind study supported the diagnosis with the Childhood Autism Rating Scale (CARS) (Elder et al. 2006). A small double blind, placebo-controlled challenge study studied 14 children between 2 and 5 years of age who all were getting similar Early Intense Behavioral Intervention (Hyman et al. 2016). Analysis of parent report data on a 90 item survey describing subjective response to the GFCF diet in 387 children included history of gastrointestinal problems (Pennesi and Klein 2012).

Treatment Procedures

The studies published in the scientific literature to date have used different procedures to educate families about implementing and maintaining the GFCF diet. The majority provided education-related implementation and ongoing support but did not describe dietary adherence. Elder et al. (2006) provided a complete diet to the families for the child under study. Hyman et al. (2016) had

a dietitian collect and examine 24-h diet diaries throughout the trial.

Study design also varied, making it difficult to compare data (Buie et al. 2010; Christison and Ivany 2006; Mulloy et al. 2009; Millward 2008). Several case series reported on open trials in which children were placed on GFCF diets (Pennesi and Klein 2012). Individual services varied, and medications and supplements that might affect behavior were permitted. Subjective and nonstandardized assessments further compromise interpretation. In two single-blind trials (Knivsberg et al. 2002; Whitely et al. 2010), the study evaluators were blinded to the group assignment, but the reporters of behavior were not. This has the potential for the parents and school personnel who know if the child is on the diet or not to report based on their bias. Double-blind, placebo-controlled approaches included a cross-over of 6 weeks on GFCF diet and 6 weeks off (Elder et al. 2006). Hyman et al. (2016) reported on double-blind placebo-controlled challenges of gluten, casein, and both and placebo in children maintained on a GFCF diet.

Efficacy Information

The efficacy of the GFCF diet was not consistent across studies. The utility of the diet varied between reported studies based on the outcome measures selected, study population, and interpretation of the data. The outcome measures are summarized in the section below.

While the popular press and Internet are replete with anecdotal endorsements of the GFCF diet, the scientific literature to date is not supportive of its use based on the clinical trials that have been published (Buie et al. 2010; Millward 2009). The studies typically are of small size. Negative studies usually need to be quite large to establish that a treatment is not useful. The largest study to date (Whitely et al. 2010) has over 50 participants but is single blind and does not control for other interventions that might have impacted change in behaviors. It did not document medical comorbidities like celiac disease or food allergies that might have impacted the response to dietary intervention. Since educational and behavioral

interventions may impact development and behavior as well (see ► [ABA](#)), interventions that are used for prolonged periods need to be evaluated in concert with other approaches that are also being used to impact symptoms.

For families who desire to implement an empiric trial of the GFCF diet, the scientific literature does not provide sufficient information to recommend a length of dietary trial or specific workup that would identify children with increased likelihood of response. The longer that a child is exposed to an intervention, the greater the likelihood that ongoing development and the other educational and behavioral interventions in place will also impact developmental gain. Many advocates of the diet recommend removal of one factor (e.g., casein) then removal of the other after an adjustment period. There is no evidence of an “addiction” to either casein or gluten to support a “withdrawal” effect. However, if an underlying intolerance to either component is the cause of irritability or GI distress, then a stepwise removal of casein and gluten might help a family determine the least restrictive diet necessary for symptomatic improvement.

If a family desires to undertake a trial of the GFCF diet, they should consult with their health-care provider regarding the potential for celiac disease, food allergy, or lactose intolerance. General allergy testing and measurement of urine peptides are not likely to be helpful. The family and therapy team can identify target behavioral data that can be collected during implementation of a trial of the GFCF diet to help determine if there is benefit. It can be as simple as structured collection of a Clinical Global Index, behavioral rating scales such as the Aberrant Behavior Checklist (see ► [ABC](#)), sleep diaries or rating scales, or formal language or cognitive testing. Some measures are not designed to measure change over short periods (e.g., ► [Autism Diagnostic Observation Schedule](#)) or cannot be administered at a frequent interval without introducing a practice effect (e.g., formal language and IQ tests). These measures may not be sensitive to subtle differences in behavior.

Outcome Measurement

The approach to measurement of behavioral effect varies between published studies, making comparison difficult. Core symptoms of ASD have been reported as subjective parent impression (Pennesi and Klein 2012) as well as through parent report using behavioral scales (GARS, Vineland) (Millward 2009; Whitely et al. 2010). Parent report captures important information; however, it also allows for significant bias if the parents are not blinded to the intervention. They, of course, knew that the diet was implemented in all but the double-blind, placebo-controlled study (Elder et al. 2006).

Core symptoms of ASD were addressed by varied approaches as well. While subjective ratings cannot be dismissed, they are not readily interpreted. Whitely et al. (2010) used the GARS to quantify the report of behaviors observed by the parents and the ADOS to document improvement over time. The ADOS as used was not developed to be used as a measure of change for symptoms of ASD (see ► [Autism Diagnostic Observation Schedule](#)). Elder et al. (2006) used the Childhood Autism Rating Scale to quantify improvement. While the families were blind as to dietary status, this instrument was not developed to measure improvement with repeat administration either (see ► [CARS](#)). The double-blind, placebo-controlled, randomized study did not identify exposure to gluten/casein as altering core symptoms of autism in the short run by the measures used.

Language and development was identified as an outcome measure in several studies. Knivsberg et al. (2002) suggested there was an improvement in formal language scores that did not reach statistical significance. Whitely et al. (2010) suggested developmental improvement over time on the Vineland during the first 6 months of intervention. Elder et al. (2006) found no change in language over the 6-week study interval.

Other behaviors that might be affected by diet were considered using several approaches. Elder et al. (2006) looked at global change without demonstrable effect.

Nutritional outcome of the GFCF diet has been examined as well. Cornish (2002) reviewed diet diaries collected by families recruited through a

postal survey. She suggested that children on restricted diets were not found to be at increased risk for nutritional deficiencies. The nutritional implications of the GFCF diet in community use over time are unknown. Hediger et al. (2008) noted decreased cortical bone density in boys with ASD that was further decreased in the presence of dietary limitation of dairy products. Stewart et al. (2015) did not identify nutritional compromise in children with ASD given a GFCF diet who were supplemented with calcium and vitamin D, but not all children on limited diets are appropriately supplemented (Marí-Bauset et al. 2016; Srinivasan et al. 2017). Ghalichi et al. (2016) used the Rome III criteria to document improvement in the gastrointestinal symptoms of children with ASD randomized to the GFCF diet. However, the report of behavioral improvement is difficult to interpret because the outcome measure was the GARS-2, a tool not designed to measure behavioral change.

Qualifications of Treatment Providers

Families considering a trial of the GFCF diet should discuss their plans with their health-care provider. Since dairy products are a major source of calcium and vitamin D for children, another source of these nutrients will need to be identified if milk and milk products are eliminated from the diet. Grain-containing products are typically supplemented with B vitamins and other nutrients and as such provide many essential nutrients in children's diets. Referral of families considering a trial of this diet to a registered dietitian for education may be helpful regarding education on foods containing gluten and casein, how to introduce new foods, nutritional monitoring, and advice regarding prudent supplementation as needed. An RD is a professional with graduate training in nutrition and state licensure. Health insurance may cover nutrition consultation depending on diagnosis.

In addition to counseling regarding nutritional adequacy of the foods their child will consume, families pursuing a GFCF diet need to be educated on reading food labels to determine which products contain gluten and casein. Gluten is present in foods labeled as containing wheat, barley, and rye. Other

ingredients containing gluten include malt, modified food starch, and others. Hidden sources of gluten may include spices dusted in flour to prevent clumping and foods fried in oil also used for gluten-containing products (e.g., oil in a restaurant used to cook both French fried potatoes and chicken nuggets with bread coating). All dairy products contain casein including milk, cheese, yoghurt, ice cream, sherbet, butter, and powdered milk. Milk proteins like casein and whey may be ingredients in packaged foods. Some vegan products like cheese substitute may contain casein. Lactose-free dairy products may contain casein or whey.

Clinicians who practice complementary, holistic, and integrative medicine may advocate for a trial of the GFCF diet with or without use of other nutritional supplements. The studies in the scientific literature do not report on combined interventions. The long-term health effects of high intake of supplements above recommended intake is unknown.

Goal Attainment of Students with ASD Using COMPASS

Lisa Ruble¹ and John McGrew²

¹Educational School and Counseling Psychology, University of Kentucky, Lexington, KY, USA

²Indiana University – Purdue University at Indianapolis, Indianapolis, IN, USA

Definition

The Collaborative Model for Promoting Competence and Success (COMPASS) is an evidence-

based parent-teacher consultation and coaching intervention that roughly doubles the Special Education IEP goal attainment outcomes of children and youth with autism spectrum disorder (ASD). COMPASS brings together parents and teachers, with guidance and support from the COMPASS consultant, to create a shared understanding of the child with ASD that integrates the essential and critical information from home and school. This holistic and ecologically informed view leads to the identification of pivotal goals within the critical social, communication, and learning skill domains that leverage other areas of development. Following the identification of contextualized and socially validated goals, an intervention plan is developed based on the child's personal and environmental challenges and supports, consistent with the stipulations of the Evidence-Based Practice in Psychology (EBPP) tripartite framework. There is experimental evidence that COMPASS results in better education goal attainment outcomes for children and youth.

Historical Background

Developed by Ruble et al. (2012a), COMPASS is a framework for helping individuals with ASD achieve optimal outcomes. The model represents an accumulation of more than 80 years of combined experience of the authors in collaboration with parents, teachers, administrators, and other personnel in the field. Developed and refined over 25 years, COMPASS is a well-validated consultation intervention to systematically develop, implement, and monitor programs for students with ASD and remains one of the few consultation approaches experimentally tested in several randomized controlled studies evaluated by an independent assessment of student progress. The COMPASS consultation approach is based on educational research that shows that empirically validated professional development models that result in sustainable changes in teacher behavior and therapeutic instruction requires ongoing coaching support that occurs within the teacher's own instructional setting and is repeated over time.

The model was adapted originally from the work of August, Anderson, and Bloomquist and was first promulgated in 1992 under the title Minnesota Competence Enhancement Program. From 1978 until 1992, with both state and federal funding and under the leadership of Nancy Dalrymple at the Indiana University (Bloomington) University Affiliated Program (UAP), the model was utilized within the UAP-based residential programs for children and youth with autism and subsequently as part of a state-wide training initiative in Indiana. During this period, after extensive data gathering, the model was modified to include the concept of balancing risk factors with protective factors for developing competency. That concept was a key to the publication of “An alternative view of outcome” (Ruble and Dalrymple 1996), which advocated for new and different ways to measure outcome by focusing on the development of competence and quality of life as central outcomes and linking these to accommodations and social and family support networks. This work helped to reaffirm the evolving model’s emphasis on collaboration and building environmental and personal supports rather than emphasizing deficits.

Extensive field testing, including the development and validation of a COMPASS professional development training package, has continued from 1992 to the present time. In 1996 the model was used as the basis of the Autism Technical Assistance Manual for Kentucky Schools, which Dr. Ruble and Dalrymple authored. School systems throughout Kentucky had the opportunity to be trained with the manual, and the Kentucky Western Education Cooperative took the lead in incorporating the model in extensive training of all their school systems over several years. This training was always specific to individual students with autism, although the underlying framework can be readily applied to children with other types of developmental disabilities that could benefit from holistic approaches to assessment and intervention. The model was used for planning purposes, to address specific behavioral problems, and to help with transition planning from pre-school to elementary school, to middle school, to high school, and to postsecondary activities. In

1998, the model served as the consultation framework for TRIAD at Vanderbilt University as part of a contract to provide consultation across the state of Tennessee and was renamed the Collaborative Model for Promoting Competence and Success of Persons with Autism Spectrum Disorder (COMPASS).

Since 2004, federal funding from several National Institute of Health grants has enabled the authors to continue to evaluate the effectiveness of COMPASS for young children and for youth preparing for postsecondary activities. COMPASS has also been studied using web-based delivery. A professional development package for training COMPASS consultants is available to support its widespread use.

Rationale or Underlying Theory

Unlike most ASD evidence-based practices that focus on a specific skill, the COMPASS framework for improved goal attainment outcomes is a comprehensive program that emphasizes interventions for the core underlying areas of social, communication, and learning skills instruction that can be targeted throughout the school day, over multiple activities and learning opportunities. Designed to bring together the people with the most frequent interactions with the student – parents, teachers, therapists, etc., COMPASS helps the team to jointly identify the key social, communication, and independent work/learning skills often missing in the educational programs of students with ASD yet have a pivotal impact on other areas of development. For example, a skill such as initiation impacts asking for help, starting a work task, and making social greetings. These pivotal goals must be identified and carefully crafted for the individual student and an evidenced-based intervention plan developed and modified based on the student’s needs, preferences, and strengths. Thus, COMPASS explicitly embraces and applies an Evidence-Based Practice in Psychology (EBPP) approach (McGrew et al. 2016), combining identification of the best empirically supported intervention with a consideration of the student’s needs and

preferences, together with the personnel and general resources available within the school, home, and community.

What differentiates COMPASS from traditional behavioral consultation is the focus on quality of life (QOL). Longitudinal outcome research in autism typically defines a good outcome when an individual achieves normal social development and independence. These outcomes, however, tend to misrepresent and underestimate the competencies and critical gains in ability that impact QOL. COMPASS is based on the developmental theory that competency is the result of reciprocal and dynamic interactions between individuals and their environments (i.e., transactional) (Ruble and Dalrymple 1996). Thus, by carefully examining and identifying environmental factors and introducing modifications to reduce individual risk factors and enhance protective factors, we can influence the development of important QOL skills (Fig. 1). Competence looks different across the lifespan and is person-specific. For example, transition to adulthood brings with it vocational decisions, as well as demands for more independent living skills and for establishing and creating lifelong supportive social connections. This requires specific instruction across social, communication, and emotional competencies to continue to be refined and utilized throughout adult life. Further, the extreme heterogeneity in ASD

requires a framework, like COMPASS, that can be helpful independent of the vast differences in language, cognitive, or social abilities that characterize the autism spectrum.

A consultation intervention is complex because it is a multilevel EBP. To conceptualize the levels, we have applied Dunst and Trivette's (2012) Framework for Evidence-Based Implementation and Intervention Practices (FEBIIP) as a model to understand COMPASS (Ruble and McGrew 2015). The FEBIIP includes three levels of assessment that differentiate between the three critical actors in consultation: the consultant, the consultees (parent, teacher, service provider), and the client (student). The first level focuses on quality assessment of the implementation practice or what the consultant does to impact the second level of the intervention practice or what the teacher, parent, and service provider does as a result of the consultant. This second level, the actual intervention, then impacts the practice outcome, indirectly in terms of what the student does as a result of the interventions delivered by the parent, teacher, and service provider, as well as the direct impacts of the three consultee actors on outcomes. These multilevel aspects account for the complexity within a consulting intervention such as COMPASS. For example, in prior research on COMPASS, we showed using serial mediation that COMPASS has an indirect impact on student IEP outcomes through changes in what the teacher does (i.e., teacher adherence) and in the identification of pivotal goals (i.e., IEP quality) (Wong et al. 2018) (Fig. 2).

Goal Attainment of Students with ASD Using COMPASS, Fig. 1 Building competency by balancing challenges and supports

Goals and Objectives

The goal of COMPASS is to support teachers, parents, and other service providers with the implementation of high-quality and effective comprehensive interventions able to be provided in the community. As a consultation intervention, COMPASS helps spread expertise to where it is needed most so that children, youth, and adults achieve their optimal outcomes through the attainment of skills in the areas of social, communication, and learning.

Goal Attainment of Students with ASD Using COMPASS, Fig. 2 FEBIIP

Treatment Participants

Everyone agrees that informed teachers and parents need support and access to ASD-specific research-based interventions that can be individualized for each student with ASD and result in meaningful outcomes. One means to this end is trained consultants, who can provide the “glue” that assembles the team to together. COMPASS assists parents and teachers in working together to create positive, meaningful, effective, and personalized programs for children and youth with ASD. The personalized approach of COMPASS supports the use of research-supported interventions. Effective implementation of COMPASS requires consultants who are competent about ASD and also able to provide effective consultation to successfully support parents and teachers and other service providers.

We have examined implementation factors associated with COMPASS outcomes at the teacher and student levels (Ruble and McGrew 2015). For example, teacher factors associated with greater goal attainment progress of children who receive COMPASS are fidelity of implementation of intervention plans, teaching quality, and decreased teacher burnout. With respect to student factors, for children with autism, child engagement, rather than IQ, language, ASD severity, or adaptive skills, accounted for goal attainment outcomes, suggesting COMPASS works equally for all children (Ruble and McGrew 2013). We also have evidence that COMPASS results in less child-related parent stress (Krakovich et al. 2016).

COMPASS is effective for improving educational outcomes for young children between 3 and 8 years of age and with high school-age students with ASD.

Treatment Procedures

The detailed procedures for implementing and evaluating COMPASS are manualized (Ruble et al. 2012a). COMPASS begins with an initial 3-hour joint session that allows for discussion between the team. Starting with the COMPASS Profile or joint summary form that summarizes independently obtained parent and teacher ratings on the student’s challenges and strengths related to social skills, adaptive/self-management, communication, problem behaviors, learning skills, and sensory avoidances and preferences, the consultant facilitates in-depth information sharing. This discussion helps pinpoint critical social, communication, and work behavior/learning goals and informs the intervention plans that are generated for each goal. Following this initial consultation are four 1-hour coaching sessions with the teacher that includes progress assessment and performance feedback monitoring. Each session is standardized and allows for assessment of student progress so that intervention modification and teacher self-reflection on the implementation of the intervention plans occurs. During coaching, teachers and students provide a video or artifact (grades, diaries) to determine student progress using psychometric equivalence tested goal attainment scaling (PET-GAS; Ruble et al. 2012b). PET-GAS represents an improvement over typical GAS, in that it controls for factors that may result in biased assessment of outcomes such as level of difficulty of the skill, measurability of the skill, and the distance between the benchmarks. After progress is determined, the implementation of the teaching plan and fidelity are reviewed. Supportive problem-solving occurs based on the performance feedback and fidelity

Goal Attainment of Students with ASD Using COMPASS, Fig. 3 COMPASS intervention

monitoring. Figure 3 shows the COMPASS activities in the white boxes for young children, and the black boxes show the adaptations for high school students.

Efficacy Information

COMPASS originally focused almost exclusively on the school setting and was developed and tested for young children with ASD. In two NIH-funded RCTs of COMPASS for young children (ages 3–8) with autism (Ruble et al. 2010; Ruble et al. 2013), COMPASS resulted in large effect sizes (Cohen's $d=1.5$; 1.1). Importantly, we were able to demonstrate success in extending COMPASS to geographically isolated areas through videoconferencing, addressing the need for service access for those in underserved areas. Next, we tested a parent-mediated version of COMPASS called **COMPASS for Hope (C-HOPE)**. C-HOPE was designed for parents of children with ASD and challenging behavior. C-HOPE was effective for decreasing child problem behavior ($p < 0.001$), increasing parent competency ($p = 0.02$), and decreasing parent stress

($p < 0.001$) (Kuravackel et al. 2018). The third intervention **COMPASS for Transition (COMPASS-T)** was tested in an RCT with high school students in their final year of school with a focus on improving IEP and postsecondary outcomes (Ruble et al. 2018). Students whose teachers received COMPASS made more progress on their IEP goals based on blinded goal attainment ratings, with a very high effect size (Cohen's $d = 2.1$) Consultants were able to deliver COMPASS-T with high fidelity, and similar to our studies of young children, teacher adherence to the implementation of teaching plans increased over time, meaning coaching sessions were essential for positive student outcomes. Further, parents and teachers reported high satisfaction; teachers reported COMPASS-T was acceptable, feasible, and not burdensome (Ruble et al. 2018).

Outcome Measurement

Data collection and progress monitoring are critical features of evidence-based interventions like COMPASS. But in special education, goals are individualized, and often the measurement

-2 Present Level of Performance	-1 Progress	0 Expected level of outcome (goal)	+1 Somewhat more than expected	+2 Much more than expected

Goal Attainment of Students with ASD Using COMPASS, Fig. 4 Example of a Goal Attainment Scale

approaches using standardized assessments are insensitive to interventions for school-age and older individuals (see Bacon et al. 2014) and are, therefore, not helpful for making data-informed decisions in practice. This is an issue that was recognized decades ago when special education researchers called for an alternative approach that allowed for assessment that could be repeated frequently and used for progress monitoring and instructional decision-making for a student with individualized goals (Carr 1979; Shuster et al. 1984).

When designing the randomized controlled trials to evaluate COMPASS, an outcome measurement tool was needed that not only had good psychometric properties (reliability, validity) when used to compare groups but also good sensitivity for detecting change and growth in skills as a result of personalized instructional plans developed from COMPASS (Ruble et al. 2019). Because of a need for a measurement approach that was broad, able to be used for any age, useful for goals that varied from child to child, meaningful, and socially valid for community-based interventions such as educational settings, goal attainment scaling (GAS) was selected. GAS is a common outcome assessment approach for intervention studies from both physical and mental health sciences and was described as a method for evaluating special education outcomes more than 40 years ago (Carr 1979). For consultation research GAS is the most frequently used method (Hurwitz et al. 2015; Sladeczek et al. 2001) for several types of research designs including single-case, quasi-experimental, and randomized controlled designs. For ASD research, GAS has been applied to several group design research

studies (c.f. Odom et al. 2013; Ruble et al. 2010; Ruble et al. 2013; Ruble et al. 2019). As mentioned earlier, we developed PET-GAS to resolve potential problems with measurement bias when using GAS when making between group comparisons.

A goal attainment scale traditionally has five benchmarks that range from −2 (present level of performance) to +2 (much more than expected). Details on how to create a GAS are available from Ruble et al. (2012a). After careful assessment of the student that is based on parent and teacher input, rating scales, observations, and other sources, a goal is developed that should be achievable by the end of the school year (0 level or expected level of outcome). After the goal is identified and developed, then benchmarks are written related to the goal (progress or −1; somewhat more than expected or +1; much more than expected or +2). Figure 4 shows an example of GAS.

Goldenhar Syndrome

Carson Kautz
Yale Child Study Center, Yale University,
New Haven, CT, USA

Synonyms

Craniofacial microsomia; Hemifacial microsomia; Oculoauriculovertebral (OAV) spectrum or dysplasia

Short Description or Definition

Goldenhar Syndrome is a congenital condition affecting the development of the eye, ear, and spine. In most cases, the syndrome affects only one side of the body, but both sides of the body can be affected. Individuals with Goldenhar Syndrome have facial asymmetry, underdeveloped or absent ear, benign growths in the eye called epibulbar dermoids or lipodermoids, and benign growths or skin tags on the ear, called preauricular appendages. Abnormalities of the spine can manifest in scoliosis, as well as vertebrae or ribs that are missing, partially formed, or abnormally fused. Problems of the heart, lungs, kidneys, and central nervous system are also common. The root cause of the syndrome is unknown, but it is associated with abnormal development of the first and second branchial arches of the fetus, which develop to form the neck and head.

Categorization

Goldenhar syndrome is part of a complex group of conditions characterized by underdeveloped jaw, facial asymmetry, benign growths or skin tags on the ear, and underdevelopment or absence of the ear (Heike et al. 2009). The relationship of these conditions to each other is not well defined; they may be distinct conditions or may describe different severities of the same

condition. Other conditions in this group include hemifacial microsomia and oculoauriculovertebral (OAV) spectrum. Although these terms can be used interchangeably, they can also refer to specific combinations of craniofacial abnormalities. Goldenhar Syndrome is characterized by these craniofacial abnormalities in addition to spinal malformations and benign growths of the eye (Gorlin et al. 2001).

Epidemiology

Goldenhar Syndrome is rare; therefore, it is difficult to estimate prevalence. Some have estimated the prevalence as high as 1 in 5600 births (Gorlin et al. 2001; Grabb 1965), while others place it as low as 1 in 45,000 (Morrison et al. 1992). Males are more likely to be affected, with the male to female ratio estimated at 3:2 (Gorlin et al. 2001). Most people with Goldenhar syndrome are the only person in their family to be affected, but there have been cases in which individuals have a chromosome abnormality, in which case the condition might be inherited. Cases of both autosomal dominance and recessive inheritance have been recorded (Heike et al. 2009).

Natural History, Prognostic Factors, Outcomes

In 1952, Maurice Goldenhar coined the term Goldenhar syndrome, including in its description the characteristic preauricular appendages, as well as epibulbar dermoids and mandibular hypoplasia, or underdevelopment of the jaw. Since then, additional symptoms have been recognized as representative of Goldenhar syndrome, namely, vertebral abnormalities and underdevelopment or absence of the ear (Feingold and Baum 1978; Gorlin et al. 1963). Current thinking varies on whether Goldenhar syndrome is a distinct syndrome or whether it is simply a severe phenotype on a spectrum of facial abnormalities. Some classify it as a phenotype included under the umbrella term craniofacial microsomia (Heike et al. 2009). Others use the term OAV spectrum to denote a

“symptom-complex” that includes Goldenhar syndrome as well as hemifacial microsomia (Gorlin et al. 1963, 2001).

Goldenhar syndrome can range from mild to severe. More mild cases may need no other treatment than careful monitoring. Children with Goldenhar syndrome have been seen to be shorter than their peers and may have delayed motor development or hearing loss (Bogusiak et al. 2017). Some speech disorders have been observed, as well as psychosocial problems and behaviors commonly associated with autism (Barton and Volkmar 1998; Bogusiak et al. 2017; Maris et al. 1999). Individuals with Goldenhar syndrome may also exhibit breathing problems, including tachypnea and sleep apnea, and feeding problems (Gorlin et al. 2001). Cleft lip, face, or palate is also commonly associated with Goldenhar syndrome. More severe expression of the disorder is associated with cerebral and cranial defects, which often are associated with intellectual disability and higher mortality (Gorlin et al. 2001; Setzer et al. 1981). Congenital heart disease is common in Goldenhar syndrome; tetralogy of fallow (TOF) and atrial and ventricular septal defects have been found to be the most common, but many types of heart problems have been seen (Digilio et al. 2008).

Clinical Expression and Pathophysiology of Goldenhar Syndrome

Clinical presentation of Goldenhar syndrome is highly variable and ranges from mild to severe. It is congenital, meaning it is present at birth. The literature is mixed and no clear diagnostic criteria have been defined for Goldenhar syndrome, but the general clinical expression is characterized by abnormalities in the eye, ear, jaw, and spine (Bogusiak et al. 2017; Feingold and Baum 1978; Gorlin et al. 2001; Heike et al. 2009). Goldenhar syndrome is set apart from other craniofacial conditions by the presence of epibulbar dermoids or lipodermoids in the eye. These are benign growths that are yellow or milky white in appearance and can range in size. Some individuals with

Goldenhar syndrome have also presented with underdevelopment or absence of an eye (Gorlin et al. 1963). Mandibular or maxillary hypoplasia or other developmental issues in the bone structure of the face are often present (Feingold and Baum 1978; Gorlin et al. 2001; Heike et al. 2009). Preauricular or auricular appendages, skin tags near or on the ear, are characteristic of Goldenhar syndrome, and malformation or absence of one or both ears is common (Gorlin et al. 2001; Heike et al. 2009). Additionally, some malformation of the inner or middle ear can be seen, with or without hearing loss. Facial asymmetry is a hallmark of Goldenhar syndrome and is often due to hypoplasia, or underdevelopment, of bones in one side of the face (Bogusiak et al. 2017). Often symptoms appear only on one side of the face, also contributing to facial asymmetry. In some cases, symptoms have appeared on both sides; in these cases, one side is often more severe (Gorlin et al. 2001). Finally, vertebral anomalies are characteristic of Goldenhar syndrome. Other symptoms not previously associated with Goldenhar syndrome, including central nervous system abnormalities, are beginning to be recognized as characteristic of the disorder, providing further evidence to support the idea of a spectrum (Gorlin et al. 2001). Goldenhar syndrome may become more severe as the individual grows older (Bogusiak et al. 2017).

Evaluation and Differential Diagnosis

Literature is mixed on the differentiation of Goldenhar syndrome from hemifacial or craniofacial microsomia, or whether Goldenhar syndrome is even distinct from these conditions. Some require the presence of epibulbar dermoids to differentiate Goldenhar syndrome from hemifacial microsomia (Gorlin et al. 1963). Some consider Goldenhar syndrome to be a phenotype under the umbrella term craniofacial microsomia. In this case, this condition is a diagnosis by exclusion, meaning it is diagnosed by ruling out disorders with similar symptoms. A common difference between Goldenhar

syndrome and other syndromes is that Goldenhar syndrome is characterized by facial asymmetry, while other craniofacial abnormalities are symmetric (Heike et al. 2009). Because of the lack of specified diagnostic criteria, many syndromes must be taken into consideration before an individual will receive a diagnosis of Goldenhar syndrome (for a comprehensive review, see Heike et al. 2009). Some examples of these syndromes are Treacher Collins syndrome, CHARGE association, and Branchio-oto-renal syndrome. Treacher Collins syndrome presents similarly to Goldenhar Syndrome, especially in underdevelopment of the ears but lacks the characteristic facial asymmetry. CHARGE association does present asymmetrically but lacks facial or preauricular appendages, as well as vertebral anomalies. Similarly, Branchio-oto-renal syndrome presents asymmetrically without vertebral anomalies; however, it can present with facial or preauricular appendages. It also usually will not include cardiac abnormalities (Heike et al. 2009). In cases such as Cat-eye syndrome and Townes-Brocks syndrome, the phenotype of the syndrome is exactly the same and so can only be differentiated through a genetic test (Heike et al. 2009).

Treatment

Because the presentation of Goldenhar syndrome is highly variable, treatment depends on the specific symptoms of the individual and often develops and changes as the individual grows older.

Due to craniofacial abnormalities, individuals with Goldenhar syndrome often have difficulty breathing and may suffer from breathing-related conditions such as tachypnea and sleep apnea, among others. A newborn diagnosed with Goldenhar syndrome or any form of craniofacial microsomia should be evaluated immediately for airway obstruction, and airway interventions will be performed in the first year of life. At the time of diagnosis, the individual should have a renal evaluation as well as a cardiac evaluation; some issues

may require immediate treatment, while some are less urgent (Heike et al. 2009).

Surgery may also be necessary early in life to correct cleft lip, cleft palate, or cleft face and to remove facial, preauricular, or auricular appendages. If cleft lip, cleft palate, or cleft face is present, the newborn will often have trouble feeding, so feeding interventions may also be performed (Bogusiak et al. 2017; Heike et al. 2009). The individual will need hearing evaluations and may require interventions such as hearing prosthetics or cochlear implants (Bogusiak et al. 2017).

More surgery may be required as the individual grows older to correct any spinal abnormalities or scoliosis, to correct dental issues, to rebuild ears or to create a prosthetic ear, and to remove epibulbar dermoids if they impair vision (Bogusiak et al. 2017). Finally, due to the higher likelihood of an individual with Goldenhar syndrome experiencing psychosocial difficulties, psychiatric or neurological evaluations and treatment may be necessary. The individual may also require speech therapy for any speech problems (Heike et al. 2009).

Grammar

Diane R. Paul
Clinical Issues in Speech-Language Pathology,
American Speech-Language-Hearing
Association, Rockville, MD, USA

Definition

Grammar, the framework for a language, consists of *syntax* (the way words are combined to convey meaning) and *morphology* (the forms of words) of a particular language.

Morphology is the system that governs the structure of words and the construction of word forms (e.g., nouns, verbs, adjectives). Morphology includes how morphemes (the smallest unit of meaning) are used to develop the rules of word formation in English, such

as adding an *s* to indicate a plural (e.g., *books*) or an *'s* to indicate possessive (e.g., *mommy's*), the use of prefixes, the use of suffixes, and so forth.

Syntax is the system governing the order and combination of words to form sentences and the relationships among the elements within a sentence (e.g., subject, object).

Individuals with speech and language disorders may have difficulty – either singly or in combination – with grammar. Speech-language pathologists assess, diagnose, and treat communication and related problems, including grammar problems.

Grand Mal Seizure

Frank Besag
Child and Adolescent Mental Health Services,
SEPT. (South Essex Partnership University NHS
Foundation Trust), Bedford, UK

Synonyms

[Tonic-clonic seizure](#)

Definition

Although this term was replaced by “tonic-clonic seizure” in 1981 (Commission on Classification and Terminology of the International League Against Epilepsy 1981), it is still sometimes used, perhaps by those who are not aware of the change in terminology. The term “tonic-clonic seizure” should be used not only because it is the current accepted terminology but also because it describes what happens. In this context, the word “tonic” means stiff and the word “clonic” means jerking. A tonic-clonic seizure is one in which the person is stiff and jerking. When the stiffening includes the respiratory muscles, a cry may be emitted at the beginning of the seizure and cyanosis may occur. The tongue is sometimes bitten. Incontinence of urine may occur. Injuries may be sustained if the patient falls. In the clonic phase, there may be copious salivation, sometimes with frothing at the mouth. If the tonic-clonic seizure is preceded by a simple partial seizure (consciousness fully retained) and/or a complex partial seizure (some impairment of consciousness), it is a secondarily generalized tonic-clonic seizure. In contrast, if there is no preceding partial seizure, it is a primary generalized tonic-clonic seizure. The sequence of events in a tonic-clonic seizure is that typically the stiffening occurs first and lasts for around 20 s, followed by rhythmical jerking, which lasts for around 45 s (Theodore et al. 1994). However, seizures can be very variable. In some people, both the stiffening and jerking appear to be present at the start of the seizure. The duration of tonic-clonic seizures can also vary greatly from one patient to another. The tonic-clonic seizure and indeed epilepsy are clinical diagnoses based on a clear description from someone who has seen the episodes. The EEG can support diagnosis but is no substitute for a good clinical history. The sequence of events in the EEG during a tonic-clonic seizure can vary from one person to another. The electroencephalogram (EEG) can also vary greatly from one individual to another. A typical situation would be that the EEG would be obscured by muscle artifact, but if the filters

allowed the underlying pattern to become evident, this would show repetitive spikes with increasing amplitude and with increasing frequency all over the brain during the tonic phase. In the clonic (jerking) phase, slow waves appear and the spikes become less frequent. After the seizure, the EEG may show nonspecific slow-wave activity in a generally suppressed record. Prolonged tonic-clonic seizures, lasting 20 min or longer (status epilepticus), are uncommon but constitute a medical emergency requiring prompt treatment to decrease the risk of permanent brain damage. The tonic-clonic seizure is one of the many types of seizures that can occur in people with autism. Estimates of the prevalence of epilepsy in people with autism vary from about 20% to 40%. The question of whether epilepsy is more common than in the general population in people with autism who do not also have learning disability (mental retardation) has been debated, but most of the evidence suggests that epilepsy primarily occurs in those who have both autism and learning disability. The relationships between epilepsy and autism continue to be debated (Besag 2009).

Grandin, Temple

Fred R. Volkmar

Child Study Center, Irving B. Harris Professor of Child Psychiatry, Pediatrics and Psychology, Yale Child Study Center, School of Medicine, Yale University, New Haven, CT, USA

Name and Degrees

Temple Grandin

- 1966 B.A. Franklin Pierce College, Concord, New Hampshire
- 1975 M.A. Animal Science Arizona State University, Phoenix, Arizona
- 1989 Ph.D. Animal Science, University of Illinois, Urbana-Champaign

Major Appointments (Institution, Location, Dates)

- Professor of Animal Science, Colorado State University, Fort Collins, CO

Major Honors and Awards

- 2010 Honorary Doctoral Degree, Duke University, Durham North Carolina

Landmark Clinical, Scientific, and Professional Contributions

Temple Grandin, Ph.D., is an animal scientist and widely known for her writing and lectures on her experience of autism. Her book *Thinking in Pictures* provides a personal and highly illuminating view of the world from the perspective of a highly able person with autism. She has written vividly about the contribution of sensory experience in autism. In addition to her advocacy, she has had an interest in approaches to treatment that involve sensory experiences. She

has also been a prominent advocate for animal welfare.

Short Biography

Born in Boston, Temple Grandin was diagnosed with autism in 1950. At that time, treatment options were limited, but she received a structured school program and communication therapy. By age 5, she was talking but recalls experiences of feeling isolated. She attended a boarding school for gifted children before going on to do undergraduate in psychology and then graduate work in animal science. In addition to her work on animal management, she has written several volumes on autism including books concerned with visual thinking, the use of pressure sensation as an intervention technique, and an autobiography.

Gray Matter

Danielle Bolling
Yale Child Study Center, New Haven, CT, USA

Synonyms

[Gray substance](#); [Substantia grisea](#)

Definition

Gray matter refers to the portion of the central nervous system composed of neuronal cell bodies, neuropil, glial cells, and capillaries. This region is so named because of its gray color (in contrast to white matter). Gray matter can be found in the cerebral cortex as well as in the thalamus, basal ganglia, and cerebellum.

Gross Motor Skills

Gianluca Esposito^{1,3,4} and Giacomo Vivanti²

¹Nanyang Technological University, Wako, Saitama, Singapore

²A.J. Drexel Autism Institute, Drexel University, Philadelphia, PA, USA

³University of Trento, Rovereto, TN, Italy

⁴Kuroda Research Unit, RIKEN Brain Science Institute, Wako-shi Saitama, Japan

Definition

Gross motor abilities entail the use of large muscle groups that coordinate body movements to perform activities such as maintaining balance, walking, sitting upright, jumping, throwing objects, etc. Gross motor skills are acquired during infancy and early childhood as part of a child's motor development and continue to be refined throughout most of the individual's years of development into adulthood. Factors that contribute to the ability and the rate that children develop their gross motor skills include both genetic and environmental influences.

The development of gross motor abilities occurs in the motor cortex, the region of the cerebral cortex that controls voluntary muscle groups.

The development of motor autonomy is the infant's main task in the first year of life. The process can be described as a series of distinct stages, where mastering each stage prepares the infant's progression to the next one. At the beginning of each stage, movement is characterized by a persistent lack of symmetry. As the stage progresses, movement becomes increasingly symmetric. During each stage, complex reflex

patterns appear and are integrated with those already existing. By 2 years of age, almost all children are able to stand up, walk, jump, walk upstairs and downstairs, and run.

Difficulties in gross motor abilities are observed in a range of conditions and have been documented in individuals with autism spectrum disorders (ASDs; Dewey et al. 2007; Lloyd et al. 2011).

Historical Background

Although both Kanner (1943) and Asperger (1944/1991) reported signs of gross motor impairment in their seminal descriptions of patients with autism, the issue of motor difficulties in this population was overlooked, until recently, in favor of research on the social and communicative deficits in this population. After 1990, and for the successive two decades, there has been a growing recognition that children with autism do experience motor difficulties (Ghaziuddin and Butler 1998; Zingerevich et al. 2009). Furthermore, the development of gross motor skills in autism and its utility as precursory sign has increasingly gained attention (Jansiewicz et al. 2006). Currently, the examination of motor abnormalities is considered to be a valuable tool for understanding the neurological basis of autism, as motor signs are easily observable and quantifiable, and they can be examined in a manner that minimizes the potential confounds of social and communicative impairments (Wodka and Mostofsky 2011). Moreover, the importance of developing specific remediation strategies to target motor difficulties is increasingly acknowledged in clinical practice (Bhat et al. 2011). Recent research is focusing on motor development (Kim 2008), motor learning (Dowell et al. 2009), motor control (Rinehart et al. 2006), preambulatory movement (Esposito et al. 2009, 2011), and the relation between motor and social-communicative symptoms in autism (Gallese et al. 2009; Gernsbacher et al. 2008; LeBarton and Iverson 2016; Setoh et al. 2017).

Current Knowledge

A range of motor atypicalities have been documented in individuals with autism spectrum disorders, including delayed walking; abnormalities in gait (e.g., toe walking), posture, balance, coordination, tone, and difficulties in higher-level motor learning tasks involving imitation and pantomime of complex gestures (Dewey et al. 2007; Gowen and Hamilton 2013; Minshew et al. 2004; Staples and Reid 2010). While motor abnormalities are not considered as a crucial feature in the diagnostic process and are not a main focus of most intervention models, literature suggests that motor impairments might be observed in individuals with autism across the spectrum and across developmental levels and chronological ages (Fournier et al. 2010). Whether motor anomalies are a universal and/or specific symptom of autism is still debated (Ozonoff et al. 2008). Similarly, it is still debated whether motor abnormalities are present and identifiable in the first year of life (Esposito et al. 2009, 2011; Ozonoff et al. 2008). This issue has far-reaching relevance with regard to early diagnosis and identification of autism. Studies investigating gross motor abilities in very young children with autism indicated that delays and/or atypical patterns in gross motor development are present between 12 and 36 months and that these differences become more pronounced with age in preschool years (Landa and Garrett-Mayer 2006; Lloyd et al. 2011). A study by Suter and colleagues found that motor difficulties at age 2 years was the clearest distinguishing factor for identifying the children who continued to meet criteria for an ASD at age of 4 years (Suter et al. 2007). Additionally, early gross motor skills have been found to predict subsequent development of language in children with ASD and those at risk for ASD (Bedford et al. 2016; Leonard et al. 2015), and preliminary evidence suggests a link between early gross motor abnormalities and social communication development in ASD (Bhat et al. 2012; LeBarton and Iverson 2016;

see also Barbeau et al. 2015). Given the paucity of studies that investigated the development of motor abilities through childhood and adulthood, it is not clear whether motor difficulties present with different features at different ages and/or whether they improve over time. More empirical research is needed to identify the age of onset and the developmental pattern of motor difficulties in autism, as well as relationship between gross motor development and later social communication abilities in these children. Recent research suggested that motor abnormalities observed in autism might reflect a developmental dyspraxia, that is, a deficit in the execution of skilled movements caused by difficulties in forming the sensory representation of the motor plan that is necessary to execute the actions (Mostofsky and Ewen 2011; Dziuk et al. 2007). While little is known about the etiology of motor impairment in autism, functional and anatomical abnormalities, as well as abnormal connectivity in the brain systems underlying motor planning and execution, have been documented in autism (Mostofsky et al. 2009; Nayate et al. 2005; Nebel et al. 2014; Qiu et al. 2010; Mostofsky et al. 2007).

Future Directions

Current studies emphasizing the involvement of the motor system in action understanding and social cognition provide an exciting avenue for future research in the field (Rizzolatti and Sinigaglia 2007; Giorello and Sinigaglia 2007). Moreover, longitudinal studies involving infants at risk for autism is starting to provide crucial information on the nature of motor impairment in autism and its relationship with social and communicative core symptoms and other motor abnormalities such as stereotyped movements (Leonard et al. 2015; Van Waelvelde et al. 2010). The increasing recognition of the importance of motor abilities in autism is leading practitioners in the field to include increasingly refined motor assessments and programs in their clinical practice.

Group Research

► Qualitative Versus Quantitative Approaches

Group Therapy

Fred R. Volkmar

Child Study Center, Irving B. Harris Professor of Child Psychiatry, Pediatrics and Psychology, Yale Child Study Center, School of Medicine, Yale University, New Haven, CT, USA

Definition

A treatment modality that makes use of group, rather than individual, format to provide counseling/support/psychotherapy.

Historical Background

Group treatments for children have their origins in the attempts to provide rehabilitation services for

children, for example, those in the juvenile justice system or in some form of congregate care. As with work with adults, approaches to group treatment have become more specialized over time, for example, in autism focusing primarily on social skills or to help children with some common situation or problems. As with other approaches to psychotherapies, there has been an increased emphasis on use of common methods and specific methods and curricula.

Current Knowledge

Various approaches to group treatment have been developed (see Moss et al. 2007). Groups can be time limited or ongoing, and they may be focused on a special issue or problem.

The role of the leader(s) may also vary so that, for example, highly focused or short-term groups may need a much more active leadership process and be more didactic.

Groups can be guided by various theoretical perspectives, and such a perspective may have implications for group composition. Groups for children and adolescents must be cognizant of the ages and developmental levels of the members. Particularly for social skills-based groups, the inclusion of typically developing peers may provide important role models. The leaders provide overall structure and ongoing monitoring and can plan and implement a range of activities. For example, for a group of more cognitively able students with autism, explicit discussion of common tasks for the age group may include an experiential component to provide practice with opportunities for feedback. For the group leaders, awareness of the group's needs and levels of functioning can guide interventions and group process as well as issues of selection of new members. Group approaches are used in a range of settings (including clinics and schools). For children, it is common to have a standard structured format with some period for group discussion, an activity and snack, and then a brief review/wrap-up. Various techniques can be used to cope with behavioral difficulties including changes in group activities or structure, verbal interpretation, limit setting,

and so forth. Sometimes an individual will not be able to tolerate the demands of being in a group, and in such cases, removal of a group member should provide an opportunity for explanation as well as discussion. Group leaders can make use of a range of intervention strategies.

Time-limited groups can be readily used with less able individuals and provide opportunities to practice social skills in a supportive context. For more cognitively able individuals, extended groups can have a broader focus on a range of issues. If typical peers are included, some degree of (often relatively minimal) preparation is needed. Support groups for parents can also be useful.

As with other psychotherapies, considerations for great treatment include the nature of the difficulties and goals, the degree to which a group approach can be helpful, and so forth. Children who are highly disruptive may be difficult to incorporate in a group treatment approach. A small body of work on the efficacy of group treatment now exists with overall results suggesting some moderate level of benefit on average.

Future Directions

There has been an increased emphasis on implementation of specific behavioral and cognitive strategies in group treatment. New approaches focus on such CBT-based approaches. Although frequently used to teach social skills, the body of actual research on group treatments in autism is rather limited.

Group Work and Class Discussions

Ruth Eren

[Cooperative groups](#)

Definition

Group work and class discussions are teaching strategies that can be found in a general education classroom. In order for students with ASD to be successful in these two learning environments, some accommodations may be needed. In group work, students are typically assigned a task to be completed by the group. Students may be assigned a specific role (e.g., notetaker) or the group may be directed to have a discussion on a specific topic or problem with the expectation that all students will equally contribute to the discussion. Students with ASD may find group work confusing unless the roles of the group members are clearly defined and written instructions for the task to be accomplished are provided. Often, step-by-step instructions for the task (task analysis) are

most helpful to the student with ASD because in addition to identifying specific steps that lead to task completion, the student sees the total process required to complete the task. In addition, the social behavior expected during the group work may need to be clearly defined and practiced through role playing prior to the inclusion of the student in a small work group. Finally, the student with ASD may need to practice discourse skills required for successful participation in a group discussion such as accepting suggestions, changing topics in a discussion, compromising, considering others opinions, negotiating, clarifying, and questioning.

Class discussions pose additional challenges for some individuals with ASD. It will be important for the teacher to make prior connections to the topic under discussion with all students, but this will be especially helpful for the student with ASD. In addition, the general topic and related vocabulary may need to be reviewed, pretaught, or “primed” with the student with ASD if they are to keep up and comprehend the discussion as it unfolds in the general classroom setting. During class discussions, the teacher can provide additional accommodations for the student with ASD by creating a visual web of information that highlights specific points and gives the student the entire picture of the topic being discussed.

Group-Based Early Start Denver Model (G-ESDM)

Giacomo Vivanti

A.J. Drexel Autism Institute, Drexel University, Philadelphia, PA, USA

Definition

The Group-Based Early Start Denver Model (G-ESDM; Vivanti et al. 2017) is an early intervention approach based on the adaptation of the Early Start Denver Model (ESDM; Rogers and Dawson 2010) for delivery within group settings. The G-ESDM emphasizes the importance of providing intensive teaching, drawing from evidence-based educational strategies, individualizing the program, and addressing multiple developmental domains within group-based cooperative learning experiences, with one adult delivering instruction to small groups of 2–3 children with ASD. Principles and strategies incorporate knowledge from developmental science, behavior analysis, and social-affective neuroscience to support learning and development in young children with autism. The group delivery format capitalizes on the feasibility, sustainability, and cost-effectiveness of providing treatment in small groups, the widespread availability of preschool programs in the community, the culturally universal tradition of educating young children in group settings, and the social and learning opportunities provided by peers.

Historical Background

The origins of G-ESDM date back to the early 1980s, when Sally Rogers and colleagues at the University of Colorado Health Sciences Center developed the Denver Model (Rogers et al. 1987), an autism intervention model informed by developmental models of autism and typical development (e.g., Rogers and Pennington 1991; Stern 1985). Subsequently, Sally Rogers and Geraldine Dawson created the “Early Start

Denver Model” (ESDM; Rogers and Dawson 2010), which involves the expansion and adaptation of the original Denver Model curriculum to address the developmental needs of toddlers, as well as the inclusion of a curriculum checklist (ESDM Curriculum Checklist; Rogers and Dawson 2010) to design individualized intervention targets. In 2010, Vivanti and colleagues at La Trobe University in Melbourne, Australia, developed the Group-Based Early Start Denver Model (G-ESDM), an approach for delivering ESDM within group-based settings, such as childcare and preschool programs. The G-ESDM was developed and implemented in the context of a partnership between the La Trobe University Olga Tennison Autism Research Center, the MIND Institute at University of California Davis, and the Victorian Autism Specific Early Learning and Care Centre, an early intervention program located at La Trobe University’s Community Children’s Centre.

Rationale or Underlying Theory

The G-ESDM, like the original ESDM, is based on cascade model of ASD (Pennington et al. 2006). According to this model, early emerging autism symptoms create a barrier to the development of the processes that facilitate bodily and emotional engagement during early interactions, such as imitation, reciprocal vocalization, and sharing of affect. Diminished participation in bodily routines that are social and playful in nature, in turn, disrupts the construction of neural specialization and behavioral knowledge in the social communication domain. As recently proposed by Dawson et al. (2005; Dawson 2008), such early disruptions might be linked to a biologically-based deficiency in experiencing social engagement as intrinsically rewarding. A corollary of this model is that targeting early social disruptions during early childhood might counteract the cascading effects of social impairments for individuals with ASD, conferring beneficial effects across different developmental domains. This is particularly important for younger children, as neural plasticity during early

developmental stages might allow for a deeper impact of social learning experiences on the developing brain.

Additionally, procedures of ESDM and G-ESDM are informed by the naturalistic application of applied behavior analysis (ABA), as articulated by Schreibman, Koegel et al. 1989 in their pioneering work on Pivotal Response Training (PRT), and more recently in the framework of Naturalistic Developmental Behavioral Intervention models of ASD (Schreibman et al. 2015).

Finally, the Group-ESDM draws heavily on the literature focused on the beneficial effects of early interaction with peers and preschool experiences for social-cognitive development. This literature indicates that the opportunity to practice complex social and cooperative behaviors during play routines with peers supports the development of social-cognitive and social emotional skills such as empathy and mentalizing (McAlister and Peterson 2007) and that involvement in high-quality child care environments that facilitate engagement in joint activities with peers has positive effects on social and communication development (National Institute of Child Health and Human Development Early Child Care Research Network 2000, 2003).

Goals and Objectives

The chief objective in the G-ESDM is to provide a sustainable evidence-based early intervention approach for young children with ASD that can be delivered in regular childcare and preschool settings. In the G-ESDM, children with ASD are provided with high-quality social learning experiences within group settings, so that the child can learn from others in their everyday experiences in their preschool program and in any other settings, and build a behavioral repertoire that support further learning and foster social-cognitive development.

While this overarching goal is relevant for all children with autism, specific treatment objectives are based on the distinctive profile of strength and weakness of each child, so that learning experiences can be individually tailored to

maximize learning progress. Individualized treatment objectives are developed from a careful assessment of the child's behavioral repertoire based on the ESDM Curriculum Checklist (Rogers and Dawson 2010), which evaluate each child's skills across multiple developmental domains including receptive communication, expressive communication, social skills, play skills, cognitive skills, fine motor skills, and adaptive skills.

Treatment Participants

The G-ESDM is designed for toddlers and preschoolers with ASD. Treatment goals are based on the ESDM curriculum, which addresses developmental skills in the 12–48 months range. The G-ESDM has been tested on children 12–60 months, with results showing better outcomes in children receiving the ESDM before 48 months of age. It has not been tested with children who have additional diagnoses like Down syndrome or fragile X.

Treatment Procedures

In the G-ESDM, individualized measurable learning objectives covering multiple developmental domains are generated every 12 weeks based on the curriculum checklist assessment. Objectives are designed to be addressed within the constraints and opportunities of group settings. Child progress is systematically recorded and mastery of all objectives is assessed every 12 weeks; new learning objectives are then generated based on the assessment results.

Individual goals are targeted within group routines. These are organized around clear, predictable, and shared goals, and designed to provide naturalistic learning opportunities, i.e., age-appropriate learning experiences involving routines and materials that children typically encounter in their everyday environments. Adults set up fun routines and play activities that naturally bring children together in the same physical space including art table activities, book activities,

“sensory” games such as games with water, sand, and shaving cream, group music and movement games such as Ring-around-a Rosie and parachute games as well as table games in which the children need to share and pass materials, or help each other. Children have duplicate objects and are face to face, so they can imitate one another, and the materials and their placement actively facilitate peer interaction. In this context, the adult organizes group-based joint activity routines, in which the children and adults in the small group are coconstructing activities that provide opportunities to do things together and learn from such experiences (Ratner and Bruner 1978). A joint activity routine is articulated in four stages, including (a) a set-up phase, in which the child gets to choose the activity; (b) a theme in which the child and the play-partners participate equally in the activity chosen by the child, creating a predictable and enjoyable routine; (c) a variation or elaboration that expands the theme; and (d) a closing phase, marking smooth ending for the current activity followed by a transition to the opening phase of the next activity. For example, a child might start to play with a piece of material (set-up phase), then the adult joins in, and the adult and child begin playing with material together, while other children are also encouraged to join in (the theme phase). As one child in the group starts engaging in a different action with the same material, the adult points that out and prompts other children to do the same (elaboration phase). When the activity starts to feel repetitive and/or children start to lose interest, the adult encourages children to close the activity and transition to the next activity (closing phase). The goal of joint activity routines is to address both the social difficulties (through the joint engagement component) and the flexibility difficulties (through the systematic introduction of variations on the theme) that characterize autism, while also providing opportunities to target multiple objectives across developmental domains.

The repeated engagement in meaningful and rewarding joint activity routines in close proximity to the peers under the guidance of the adult provide the framework for targeting and practicing expressive and receptive

communication, turn taking, imitation, sharing of affect, joint attention, functional and symbolic play, and motor skills, using evidence-based instructional techniques based on naturalistic developmental behavioral intervention, including the use of “Antecedent–Behavior–Consequence (ABC)” sequences, shaping, fading, prompting, chaining and error correction procedures, peer-mediated teaching, active management of affect, arousal, and motivation, and the use of warm, playful shared interactions as a context for learning (see Vivanti et al. (2017) for details).

A series of “decision trees” are used in the G-ESDM to readjust the program when data show that progress is slower than expected in one or more developmental areas. Modifications might include increasing the amount of teaching episodes delivered to the child during group activities, organizing 1:1 focused teaching sessions in a distraction-free environment, increasing reinforcers strength, and introducing augmentative communication tools.

The G-ESDM group activity fidelity tool (Vivanti et al. 2017) is used to determine whether the program is being delivered according to the G-ESDM implementation standards.

Efficacy Information

Preliminary evidence for effectiveness of the G-ESDM is documented in a controlled study involving 57 children with ASD ages 18–60 months, of whom 27 received 12 months of 15+ h per week of G-ESDM with staff ratios of one adult to three children (Vivanti et al. 2014). This group was compared to a carefully matched group of 30 children receiving 15+ h of early intervention for 12 months delivered in high-quality preschools that used a combination of empirically based intervention practices. Children in the G-ESDM group showed a significant advantage in overall developmental rate and receptive language scores. Additional research documented that children with younger chronological age and more advanced skills in object play, joint

attention, and imitation experienced the largest gains (Vivanti et al. 2013, 2016).

Outcome Measurement

Within the G-ESDM, there is a strong emphasis on daily tracking of a child’s progress against each learning objective. Consistent with the ESDM procedures detailed in Rogers and Dawson (2010), child’s response to each learning opportunity is recorded according to a time interval recording system, with adults taking data at between 10 and 15 min intervals depending on the frequency and intensity of teaching opportunities. These data are then summarized on each child’s “data summary sheet” on a daily basis. Measurable progress is expected on every objective within a 1–2-week period and mastery of all objectives is assessed every 12 weeks. Based on the assessment results, new objectives are written and broken down into small teachable steps, and new data sheets are developed. For research purposes, annual progress has been measured through standardized tests measuring cognitive functioning (Mullen Scales of Early Learning; Mullen 1995), adaptive behavior (Vineland Scales of Adaptive Behavior, Sparrow et al. 2005), and severity of autism symptoms (Autism Diagnostic Observation Schedule; Lord et al. 2012).

Qualifications of Treatment Providers

Professionals certified as ESDM therapists might deliver the G-ESDM following the manualized guidelines in Vivanti et al. 2017. Certification in ESDM involves completion of multiple levels of training according to the steps detailed here https://www.ucdmc.ucdavis.edu/mindinstitute/research/esdm/pdf/certification_steps.pdf.

Professionals from a wide number of disciplines are eligible to be trained as ESDM therapists, including occupational therapy, physical therapy, speech and language pathology, early

childhood education, early childhood special education, clinical child psychology, and school psychology.

Definition

Guanfacine is an alpha-2 agonist medication that has properties in common with clonidine. Early studies in adults with hypertension showed that it was less likely to cause sedation. In addition, it appeared to be less potent as antihypertensive medication. Studies done in animals showed that guanfacine also had other properties that are different from clonidine. These studies showed that guanfacine improved performance on delayed memory test in primates. In the early 1990s, studies of guanfacine in children with various conditions targeting hyperactivity and impulsive behavior began to emerge. These trials used the immediate-release product. Most trials were small and few were placebo-controlled. The immediate-release form of guanfacine has been examined in two studies in children with autism spectrum disorders. These studies suggest that the medication is helpful for reducing hyperactivity,

impulsiveness, and distractibility in these children. However, these studies were small and not definitive.

More recently, a long-acting formulation of guanfacine has been studied in two large-scale trials and also has been studied in a long-term extension trial. This new product is approved for the treatment of children with ADHD. The long-acting form of guanfacine is now approved for treatment of ADHD. Adverse effects of guanfacine are similar to clonidine. However, it does appear to be less likely to cause sedation that is often observed with clonidine. Midsleep awakening and irritability have been observed in studies of children with guanfacine. As with clonidine, guanfacine does not usually cause problems with hypotension. However, pulse and blood pressure are routinely monitored when children are treated with these compounds.

Guardianship

A guardianship is the process whereby one person assumes the legal responsibility for protecting the personal and property interests of another person who is unable to adequately do so due to physical incapacity, mental incapacity, or immaturity of age (infancy). Guardianship effectively replaces the judgment of the legally incompetent or incapacitated person (the ward) with that of the capable person (the guardian). A guardian may be an actual person, professional or nonprofessional, or a “legal person” such as a state agency, a private nonprofit organization, or a private for-profit organization. Regardless of their specific identities, all guardians must scrupulously act in good faith to protect their wards’ interests. If they fail to do so, the courts can remove and replace them. State law controls guardianship regulations and procedures, with each state determining the conditions, provisions, and specific terminology of guardianships within its jurisdiction. Guardianship laws generally prefer that courts appoint qualified and willing family members as guardians but also allow them to appoint nonrelatives when doing so would better serve the needs of the wards.

Due to the loss of personal freedom that results from the appointment of a guardian, guardianship proceedings must follow a careful and orderly legal process that ensures that the ward’s legal rights will be fully protected. Guardianships are not always permanent: adult guardianships can be terminated if the adult wards can demonstrate that

they have regained or acquired the necessary competence to care for their own needs, and guardianships of children can be terminated once the children reach the age of legal maturity.

Some types of relevant guardianships include:

Guardianship of the person. The guardian is responsible only for the ward’s personal welfare.

Guardianship of the estate (or conservatorship). The guardian is responsible only for the ward’s property; such guardians may be called “conservators.” While complete mental incompetence of the property owner is not required, his or her incapacity to adequately manage his or her property must be demonstrated.

Plenary guardianship. The guardian is responsible for all aspects of the ward’s personal welfare and property.

Limited guardianship. The guardian assumes authority only for those specific areas in which the ward is unable to make his or her own competent decisions. Limited guardianships are rarely created.

Standby guardianship. A guardian is chosen in advance by a child’s parents to assume future responsibility for the child’s welfare only if the parents become unable to do so.

Guided Compliance

Shaunessy Egan
Center for Children with Special Needs,
Glastonbury, CT, USA

Definition

Guided compliance procedures characteristically involve the systematic delivery of progressively more intrusive prompts. The prompts are delivered contingent upon an individual's non-compliance. The type of prompts used may include verbal prompting, model prompting, and/or physical guidance. These prompts are methodically increased following noncompliance with less-intrusive prompts, eventually culminating with full physical guidance when necessary.

Interventions using guided compliance have been successfully implemented to decrease noncompliance.

Habit Reversal

Douglas W. Woods and Matthew R. Capriotti
Department of Psychology, University of
Wisconsin-Milwaukee, Milwaukee, WI, USA

Definition

Habit reversal training (HRT) is a multi-component treatment package primarily used to treat tic disorders and body-focused repetitive behavior disorders such as skin picking, nail-biting, and hairpulling (trichotillomania; TTM). The first primary component of HRT is awareness training, in which the therapist works with the patient to identify instances of the target behavior, insuring the patient has, or develops, the ability to detect when the behavior occurs in real time.

After the patient is adequately aware of the behavior, competing response (CR) training

begins. In CR training, the patient and therapist identify a socially inconspicuous behavior that is physically incompatible with the target behavior, easy to perform in a variety of settings, and acceptable to the patient. The patient is taught to do CR for a prescribed period of time whenever the target behavior begins or is about to begin. The client practices using CR in session. The therapist provides praise for appropriate use of CR and prompts the patient when he or she does the targeted behavior but does not do CR. After the patient is trained to use CR in session, he or she is instructed to use it whenever the target behavior occurs or whenever he or she feels the urge to engage in the target behavior.

The final component of HRT is social support. In social support, a parent, spouse, or other individual who has a close relationship with the patient is taught to the use of HRT skills in the patient's day-to-day life. Social support ensures that HRT skills (especially the use of CR) generalize to settings beyond the therapy session. The support person is taught to praise the patient for using CR exercises and to provide gentle reminders to use CR when the target behavior occurs but CR does not.

Historical Background

The first evidence of HRT's efficacy emerged in a 1973 study by Nathan Azrin and Gregory Nunn. Throughout the 1970s and 1980s, a series of

small-n and group design studies built an initial evidence base suggesting that HRT was an efficacious treatment for tics and body-focused repetitive behaviors. More recently, larger controlled trials have lent support for HRT as a viable treatment option (either in place of or as an adjunct to drug therapy) to treat TTM, chronic tic disorders (e.g., Tourette syndrome), and other repetitive behavior problems. Within the field of tic disorders, a series of randomized controlled trials showed that patients who received HRT experienced greater symptom reduction than those on a wait list or those who received active control therapy (i.e., supportive psychotherapy). The largest of these trials showed that eight 1-h sessions of comprehensive behavioral intervention for tics – a manualized treatment centered on HRT’s core components – produced greater tic reductions than education and supportive psychotherapy and yielded gains comparable to those found with standard pharmacological treatments for tics.

Rationale or Underlying Theory

Across all problems for which the treatment is used, HRT is believed to increase awareness of behaviors that occur rapidly and often out of conscious awareness. In addition, it is believed that HRT may disrupt the underlying reinforcement processes serving to maintain a particular condition. For example, in persons with tics, aversive sensory experiences known as “premonitory urges” are known to build up immediately prior to a tic and are relieved immediately after the tic. This reduction in the aversive premonitory urge is believed to reinforce the tic. HRT physically prevents the tic from occurring and providing subsequent relief, which then allows the patient to habituate to the urge rather than eliminating it through ticcing. Over time, the urge becomes weaker with respect to eliciting tics. Similar reinforcement patterns are disrupted in the use of HRT to treat TTM. A large reinforcer for pulling involves the tactile stimulation that comes from the act of pulling. When the patient does CR at the beginning of the pulling act, the

tactile reinforcement that is usually received does not occur, and ultimately the pulling is decreased.

Goals and Objectives

HRT is intended to address tic disorders (e.g., Tourette syndrome) along with a variety of body-focused repetitive behavior disorders such as nail-biting, thumb-sucking, TTM, stereotypies, and skin picking. Like behavioral approaches to the treatment of other disorders, HRT takes a pragmatic, present-focused approach whose primary aim is reduction of the target behavior. When used as a treatment for neuropsychiatric conditions such as chronic tic disorders, HRT does not propose to “cure” the affected individual but rather teach skills that can effectively aid symptom management. HRT can be used either alone or in combination with pharmacotherapy or other treatments. As the severity of chronic tic disorders and TTM can wax and wane over time, the frequency with which a patient uses HRT skills at a given point in time may also vary. Evidence suggests that HRT skills are retained long after acute treatment ends (see section “[Efficacy Information](#)”) and therefore serve as a long-term tool for self-management of repetitive behavior disorders.

Treatment Participants

HRT is effective for both children and adults. Most studies evaluating HRT have been done with patients who have IQ > 80; however, clinical observation suggests that patient’s motivation for change, receptive language abilities, and instruction following skills are critical to the success of HRT. Also, research has shown that general deficits in response inhibition predict poor response to HRT for adults with tic disorders. Patients with deficits in these areas, either due to young biological age or delays in language and/or cognitive development, may struggle with traditional HRT. Nevertheless, the core components of HRT could be implemented in a fashion that does not rely as much on patient self-management skills. For

example, awareness training could consist of reinforcing a specific, subtle response such as raising a finger immediately after the occurrence of the behavior (a type of tacting) to indicate awareness. After this skill is mastered, chaining procedures could then be used to teach the patient to perform the competing response after the finger-raising response, thus mimicking the typical CRT requirement that patients perform the competing response after the occurrence of the targeted behavior.

To date, two published studies have demonstrated the potential effectiveness of modified HRT procedures as part of effective treatments for repetitive behaviors in individuals with intellectual disabilities and/or autism. The modification included physical prompting by the therapist during AT and the use of differential reinforcement and auditory feedback to augment the “self-management” style of HRT intervention. Although more research on the viability and efficacy of such adapted forms of HRT should be conducted, these studies serve to demonstrate the potential utility of HRT in individuals with autism spectrum disorders and intellectual disabilities who may have deficits in language and instruction following skills.

Treatment Procedures

HRT is delivered on a flexible outpatient basis, which is typically acceptable to consumers. Research has shown benefits resulting from as little as one or two HRT sessions, but typically HRT has been implemented across 8–10 weekly sessions lasting approximately 1 h each. Treatment is usually delivered in an individualized, face-to-face format, though research has shown that the treatment can be effective in groups and when implemented via remote teleconferencing equipment.

Since HRT skills involve a “self-management” repertoire employed by the individual himself or herself (i.e., are ultimately to be performed in the absence of prompts from others), it is important that the treatment be acceptable to the patient and able to be practically implemented in the patient’s

day-to-day environment. To ensure this, HRT employs open dialogue between the therapist, patient, and parent or others close to the patient. The core role of the HRT therapist is to teach HRT skills involved in AT and CR training, as well as to educate the support person, devise an appropriate reward system, and to work in concert with other treating professionals and parents to ensure smooth implementation of the intervention.

Efficacy Information

A large evidence base exists to support the use of HRT for body-focused repetitive behavior disorders. A series of small-n and uncontrolled studies throughout the 1970s–1990s showed that HRT tends to provide rapid reductions in symptom severity that are fairly durable following the cessation of treatment. Research has also shown that relapses do sometimes occur, but can most often be ameliorated by the inclusion of one or more posttreatment “booster sessions” in which HRT skills are briefly reviewed and practiced.

Throughout the past 20 years, the bulk of research on the efficacy of HRT has shifted to the study of Tourette syndrome and other chronic tic disorders. Researchers have conducted a series of randomized controlled trials, confirming that HRT is superior to wait list and active control treatments. In the largest of these studies, children with chronic tic disorders and Tourette syndrome received either an HRT-based intervention or psychoeducation plus supportive psychotherapy (as a control condition). Fifty-three percent of those receiving HRT showed clinically meaningful improvement following the acute phase of treatment (compared to 17% of those in the supportive psychotherapy condition), and 87% of these patients maintained treatment gains at the 6-month follow-up. The magnitude of the symptom reduction observed in the HRT group was comparable to the reduction of symptoms reported in studies evaluating pharmacological treatments for tics.

Although children with autism experience a higher prevalence of chronic tic disorders than typically developing children (Baron-Cohen

et al. 1999), stereotypies are by far the most common repetitive behavior problem seen in children with autism and related disorders. HRT has been far less studied as a treatment for stereotypy compared to chronic tic disorders, but the single published study investigating HRT for stereotypy in typically developing children found that HRT was an effective treatment. This finding, combined with the finding that HRT can be modified and taught to individuals with language deficits, sets the stage for future research investigating the application of HRT for tics and other repetitive behavior problems in children with autism spectrum disorders.

Outcome Measurement

The selection of tools to assess outcomes will depend on the age of the patient as well as the target behavior. For some behaviors, such as nail-biting and skin picking, permanent product measures such as the length of fingernails or the size of picking-induced wounds may be used to evaluate the severity of the behavior. However, other behaviors treated with HRT do not yield an obvious product, and other methods of evaluation must be used. Calculating the frequency with which the behavior occurs during a specific observation period has high face validity, but has significant limitations which preclude its use as a stand-alone measure of behavior. In addition, tics and many other repetitive behaviors often occur in the absence of others and are heavily influenced by minute-to-minute contextual variables such as physical setting, fatigue, and stress, thus making direct observation more difficult.

To overcome these difficulties, clinical researchers have developed interview-based, parent-report, and self-report assessment tools. Examples of tic assessments include the Yale Global Tic Severity Scale (YGTSS; validated for ages 5 and above), the Parent Tic Questionnaire (PTQ; validated for ages 7–16), and the Premonitory Urge for Tics Scale (PUTS; valid for ages 10 and above). The Massachusetts General Hairpulling Scale (valid for adults), the Milwaukee Inventory for Styles of Trichotillomania (MIST-A, adult version valid for ages 18 and

above; MIST-C, child version valid for ages 10–17) can be used to assess TTM, while the Skin Picking Scale (SPS; valid for adults) and the Milwaukee Inventory for the Dimensions of Adult Skin Picking (MIDAS; valid for adults) can be used to assess skin picking. The Stereotypy Severity Scale can be used to assess stereotypies. Due to the strengths and weaknesses of each type of assessment, clinicians should use multimodal assessment both at intake and throughout treatment to monitor symptom severity and the patient's response to the intervention.

Qualifications of Treatment Providers

Like any form of therapy, HRT should be implemented only by adequately trained behavioral health professionals, who are knowledgeable in the presenting problem. Although no formal certification process currently exists, it is recommended that HRT training involve didactic instruction through graduate courses or through one of the many workshops on HRT and related techniques that are regularly offered throughout the United States and other countries. In addition, it is recommended that practitioners interested in learning HRT be supervised for the first few cases by someone well versed in the procedure. HRT-based treatment manuals have been devised for many disorders, and health professionals trained in other forms of behavior therapy may be able to effectively administer HRT with the manuals as therapeutic guides.

Hair Analysis

Madison Pilato
Neurodevelopmental and Behavioral Pediatrics,
University of Rochester Medical Center,
Rochester, NY, USA

Synonyms

[Commercial hair analysis](#); [Hair mineral analysis](#);
[Hair trace metal analysis](#)

Definition

Hair analysis is an approved method for determining trace element concentrations and exposure to heavy metals (World Health Organization 1990).

Scalp hair is removed and sent to a laboratory for analysis. The most common elements analyzed by laboratories in the United States, as determined by Seidel et al. (2001), include aluminum (Al), arsenic (As), calcium (Ca), cadmium (Cd), cobalt (Co), chromium (Cr), copper (Cu), iron (Fe), mercury (Hg), potassium (K), magnesium (Mg), manganese (Mn), molybdenum (Mo), sodium (Na), nickel (Ni), phosphorus (P), lead (Pb), selenium (Se), and zinc (Zn).

Many children with autism are selective eaters, leading to concerns about possible nutritional deficiencies. Additionally, trace metals are related to neurotransmitter synthesis and brain electrochemistry and therefore have the potential to affect neurological function. These concerns inspired several studies performed during the 1980s in which the hair of children with autism was analyzed and compared to controls for trace elements. The results of these studies did not show consistent differences between individuals with and without autism (Shearer et al. 1982; Wecker et al. 1985; Gentile et al. 1983), and hair analysis became less prevalent in the autism literature.

Hair analysis became relevant to autism again because of a proposed relationship between mercury exposure and the development of autism (Bernard et al. 2001). Hair analysis was adopted as one technique to test for unusual mercury levels, in addition to other elements. Holmes et al. (2003) determined that mercury levels were reduced in the results of hair analysis of children with autism compared to control children. The authors explained this observation by claiming that children with autism have a reduced ability to clear mercury from their bodies. In contrast, Fido and Al-Saad (2005) discovered elevated levels of mercury, lead, and uranium in the hair of children with autism. Other studies (Ip et al. 2004; Williams et al. 2008) have found no differences in hair mercury levels between children with autism and control children.

Results from commercial hair analysis should be interpreted with extreme caution. Barrett (1985) reported the lack of inter- and intra-laboratory reliability of 13 commercial hair analysis laboratories. In 2001, Seidel et al. confirmed the lack of interlaboratory reliability even after considerable technological improvements.

Similarly, laboratories used different techniques (e.g., atomic emission, mass spectroscopy), and without any existing proficiency testing programs, each laboratory was responsible for its own verification method and criteria for accuracy. At the time of publication, Seidel et al. reported that there were no regulation standards among commercial hair analysis laboratories.

Similarly, Steindel and Howanitz (2001) advised clinicians that no standard method for commercial hair analysis exists. However, they give several suggestions for choosing a good laboratory. The best laboratories will give proof of certification or accreditation, an explanation of the specific washing and digestion procedures, and information about recovery rates, minimum detection limits, and internal quality control. The World Health Organization (1990) recommends the neutron activation procedure as the most accurate and sensitive procedure. Lind et al. (1988) found good interlaboratory agreement for this method. Another widely used and accepted procedure is the selective atomic absorption (“Magos”) method.

Alti-Haloperidol; Apo-Haloperidol; Haldol™;
Novo-Peridol; Peridol; Pms-Haloperidol; Ratio-
Haloperidol

Definition

The brand name of haloperidol in the United States is Haldol. Canadian brand names include Alti-Haloperidol, Apo-Haloperidol, Novo-Peridol, Peridol, Pms-Haloperidol, and Ratio-Haloperidol. It comes in three forms: a pill, an intramuscular injection, and a longacting depot decanoate form and is manufactured by Ortho-McNeil-Janssen Pharmaceuticals, Inc.

Indications

The oral and immediate-release injection forms of haloperidol are FDA-approved for the treatment of schizophrenia as well as for tics and vocal utterances associated with Tourette's disorder (Janssen 2005). These forms are also used as second-line treatment to manage hyperactivity in the pediatric population as well as for severe behavior problems, particularly combativeness, explosiveness, and hyperexcitability (Stahl 2009). The long-acting depot intramuscular decanoate form of haloperidol is approved for the treatment of schizophrenia in situations where prolonged parenteral antipsychotic therapy

is needed. Haloperidol is not approved for use in the treatment of autism or any other autism spectrum disorder (ASD).

Mechanisms of Action

Mechanism of Action, According to Stahl (2008).

Haloperidol is a conventional antipsychotic, also known as a “first-generation” or “typical” antipsychotic. The precise mechanism of action is not clearly established, but it is believed to antagonize postsynaptic dopamine-2 (D₂) receptors in the brain. One of haloperidol's most notable roles is D₂ receptor antagonism in the mesolimbic pathway is diminishing the symptoms of psychosis. The introduction of this drug class resulted in relief to individuals living with schizophrenia and associated psychotic illnesses by reducing perceptual disturbances, such as hallucinations and delusions. The downside is that the mesolimbic pathway is believed to moderate the brain's reward and reinforcement system. Blockade here can also result in decreased pleasure, anhedonia, apathy, and reduced social interest, often referred to as “secondary negative symptoms.” This is further exacerbated by dopamine blockade in the brain cortex and mesocortical pathways. Blockade of the dorsolateral prefrontal cortex can lead to worsening cognition, whereas blockade of the ventromedial prefrontal cortex can lead to worsening affective symptoms, like depression.

The benefit of D₂ receptor antagonism in the nigrostriatal dopamine pathway is reduction of tics and other symptoms of Tourette's disorder. However, disproportionate dopamine blockade in this area can mimic the pathophysiology of Parkinson's disease. When the amount of dopamine available to the postsynaptic receptor is excessively diminished, Parkinsonian-like side effects can occur including stiffness, cogwheeling, and tremor. Since the nigrostriatal pathway is part of the brain's extrapyramidal nervous system, these side effects are referred to as extrapyramidal symptoms or EPS. Continued, long-term blockade of nigrostriatal D₂ receptors can result in a hyperkinetic movement disorder

known as tardive dyskinesia, involving involuntary movements of the face, jaw, tongue, extremities, or torso. This may present like chewing, facial grimacing, jerking of the arms or legs, or even rhythmic, fluid dancing of the body known as chorea. These side effects may be reversible if the drug is stopped early enough, but there may be a point in chronic therapy when it is too late. It is hypothesized that chronic antagonism of D₂ receptors may cause them to permanently become hypersensitive or increase in number, leading to irreversible tardive dyskinesia.

D₂ receptor antagonism in the tuberoinfundibular pathway causes elevated plasma prolactin levels. This can result in amenorrhea (irregular menstruation) in women and galactorrhea (breast secretions) in either men or women. It may also interfere with fertility, particularly in women, as well as bone mineralization in postmenopausal women, raising their risk of osteoporosis.

Haloperidol is also selective in its affinity for the alpha-1 adrenergic receptors, which can lead to orthostatic hypotension, dizziness, and drowsiness. Unlike other conventional antipsychotics, it has minimal affinity for cholinergic or histaminic receptors and therefore puts the patient at risk for increased EPS.

Specific Compounds and Properties

Haloperidol generic and immediate-release injection: 4-[4-(*p*-chlorophenyl)-4-hydroxypiperidine]-4'-fluorobutyrophenone (Janssen 2005).

Haloperidol decanoate for long-acting injection: 4-(chlorophenyl)-1-[4-(4-fluorophenyl)-4-oxobutyl]-4-piperidinyl decanoate (Janssen 2005).

Clinical Use (Including Side Effects)

Haloperidol comes in a generic pill form, an immediate-release intramuscular injectable form called Haldol Injection, and a long-acting injectable form called Haldol Decanoate. Haloperidol can be sedating, so both the oral or intramuscular

forms are often used to stabilize acutely agitated patients with moderately severe to very severe symptoms (Janssen 2005). Haloperidol is used in the short- and long-term treatment of psychotic illnesses, particularly in diminishing symptoms of schizophrenia, like hallucinations and delusions (Stahl 2009). It is also used as management for tics and involuntary vocal utterances associated with Tourette's disorder. In the pediatric population, haloperidol can be used to manage hyperactivity and severe behavioral disturbance, particularly combativeness, explosiveness, and hyperexcitability. Safety and efficacy have not yet been established in children and adolescents, so haloperidol should be considered second-line treatment for these conditions behind the atypical, second-generation antipsychotics that are approved for use in the pediatric population. Oral and intramuscular haloperidol is commonly given to patients once or multiple times daily, depending on their clinical presentation and medication needs. The long-acting depot decanoate form is approved for the treatment of schizophrenia where prolonged parenteral antipsychotic therapy is needed and given as a monthly injection.

Caution should be used when administering haloperidol to individuals with cardiovascular disorder due to a risk of hypotension and/or precipitation of anginal pain (Janssen 2005). Haloperidol also decreases the seizure threshold and should therefore be used with caution in patients being treated with anticonvulsants. There are no well-controlled studies with haloperidol in pregnant women, so the effect on the fetus is unknown. Haloperidol is a pregnancy category C drug, meaning there are some animal studies demonstrating adverse effects but no controlled studies in humans. Haloperidol therefore should only be used in pregnancy (or in women likely to become pregnant) if the benefit clearly outweighs the risk.

Clinical Uses in Autism Spectrum Disorders

Haloperidol is the most critically studied antipsychotic medication for managing or reducing symptoms associated with autism (Malone and Waheed 2009). The earliest double-blind,

placebo-controlled studies examined the efficacy of haloperidol in treating symptoms associated with autism such as repetitive behavior, stereotypies, hyperactivity, mood lability, learning, language acquisition, and sociability in autistic children between the ages of 2 and 7.5 years (Anderson et al. 1984, 1989; Campbell et al. 1978; Cohen et al. 1980). Overall, these studies found haloperidol to be efficacious in alleviating many of these symptoms with minimal side effects, although these were short-term studies that did not extend beyond 4–14 weeks. Other studies have compared the safety and efficacy of haloperidol with other drugs in treating autistic disorder and were overall successful (Faretra et al. 1970; Miral et al. 2008; Naruse et al. 1982; Remington et al. 2001). These latter studies looked at broader age ranges and included older children, adolescents, and some adults. There has been one long-term placebo-controlled study showing the efficacy of discontinuous haloperidol treatment over the course of 6 months in children with autism, but the results are somewhat limited by the study population as it only included children who responded favorably to haloperidol in the past (Perry et al. 1989). The results are intriguing nonetheless and have been included in this summary of double-blinded, placebo-controlled studies examining haloperidol in the treatment of autism.

Short-Term Research (4–14 Weeks)

In a study by Campbell et al. (1978), haloperidol was found to be superior to placebo in reducing stereotypies and social withdrawal in 40 children diagnosed with autism aged 2–7 years over the course of 12 weeks. Participants received dosages between 0.5 and 4.0 mg/day with a mean of 1.65 mg/day. Interestingly, children who received both medication and behavioral treatment improved the most in acquiring imitative speech, making it one of the first reports showing that combined treatments produced superior results (Malone and Waheed 2009). Excessive, dose-related sedation was the most common side effect. Another study by Cohen et al. (1980) demonstrated decreased stereotypies in autistic children ages 2–7 using haloperidol over the course of

10 weeks. In both of these studies, acute dystonia was observed in a few participants as an adverse event. Another study by Anderson et al. (1984) showed that haloperidol resulted in significantly reduced behavioral symptoms, general clinical improvement, and greater facilitation and retention of discrimination learning in 40 autistic children ages 2–7 years over 14 weeks. There were no adverse effects noted at therapeutic doses, which ranged from 0.5 to 3.0 mg/day (0.019–0.217 mg/kg/day). Anderson et al. (1989) described haloperidol as a “powerful drug in reducing, both statistically and clinically, maladaptive behaviors” including decreased hyperactivity, temper tantrums, withdrawal, and stereotypies. The sample of 45 children in this study were inpatients whose symptoms ranged from moderate to severe and whose ages were between 2 and 7.5 years. Medication dosages ranged from 0.25 to 4.0 mg/day. During the 4-week course of treatment, no adverse side effects were noted.

Haloperidol has been compared to two other conventional antipsychotics in the management of autism: fluphenazine in 1970 by Faretra et al. and pimozide in 1982 by Naruse et al. Each of these drugs demonstrated efficacy, but in comparison, haloperidol was found to be more effective than fluphenazine in reducing withdrawal, aggression, and stereotypies. Acute dystonic reaction, akathisia, and sedation were observed side effects. A 2001 study by Remington et al. compared haloperidol to clomipramine, a tricyclic antidepressant with potent serotonin reuptake inhibiting (SSRI) properties, in managing withdrawal, stereotypy, hyperactivity, and affective lability in autistic disorder. This study examined 36 children and adults between the ages of 10 and 36 years over 7 weeks. Both drugs demonstrated comparable improvement in symptoms when compared to baseline, but unfortunately, a significant number of participants were unable to complete the study due to side effects and lack of efficacy with clomipramine. The study favored haloperidol over clomipramine in the treatment of autistic disorder, particularly for hyperactivity and irritability but also in global symptom severity. Clomipramine was not better tolerated nor was it superior to

haloperidol in the management of stereotypy, as was originally hypothesized. In 2008, Miral et al. compared the safety and efficacy of haloperidol to risperidone, a second-generation antipsychotic that is believed to antagonize dopamine-2 receptors, serotonin 2A receptors, and other serotonin receptors in the treatment of autistic disorder. This study examined 30 children aged 8–18 years for 12 weeks, with dosages ranging from 0.01 to 0.08 mg/kg/day. Although both drugs were found to be safe and well tolerated in the treatment of autistic disorder, risperidone was more effective in treating impulsivity, behavioral symptoms, language skills, and impaired sociability. Risperidone led to a greater increase in prolactin, whereas haloperidol resulted in increased alanine amino transferase (ALT).

Long-Term Research (6 Months or More)

In a 1989 study by Perry et al., haloperidol demonstrated efficacy when dosed continuously and discontinuously (5 days taking haloperidol and 2 days taking placebo) in children who had previously responded favorably to haloperidol. The children ranged in age from 2 to 8 years and showed a reduction in many maladaptive symptoms, with the most response in those with irritability, labile and angry affect, and uncooperativeness. Although the two groups were not matched to placebo, a subset of these children who were switched to placebo after the study has discontinued required additional haloperidol treatment for the recurrence of severe symptoms, supporting the drug's efficacy.

Side Effects, per Ortho-McNeil-Janssen Pharmaceuticals

Cardiovascular side effects include hypotension, tachycardia, and hypertension. QT prolongation and ventricular arrhythmias have been reported.

Central nervous system (CNS) side effects include Parkinsonian-like symptoms like tremor, rigidity, or cogwheeling; akathisia (inner restlessness); dystonias; or tardive dyskinesia. Dystonias are prolonged contractions of muscles and can include neck muscle spasms, tightening of the throat, dyspnea, or tongue protrusion. These can occur at low doses but are known to occur more frequently and with greater severity at higher

doses. They are also more often seen in males and younger age groups. Administering anticholinergic medication can limit or reduce these effects. Tardive dyskinesia is the potentially irreversible syndrome of involuntary, dyskinetic movements (see Mechanism of Action). Haloperidol reduces the seizure threshold and therefore increases the risk of seizures. Other CNS side effects can include insomnia, anxiety, euphoria, agitation, drowsiness, depression, headache, confusion, sedation, dizziness, and vertigo.

Neuroleptic malignant syndrome (NMS) is a potentially fatal adverse effect of using any antipsychotic medication. It presents as hyperpyrexia, muscle rigidity, altered mental status, and autonomic instability. This includes dysrhythmias, irregular blood pressure, tachycardia, or diaphoresis. It can lead to elevated creatinine phosphokinase, myoglobinuria from muscle breakdown, and acute renal failure.

Autonomic reactions can include dry mouth, blurred vision, urinary retention, diaphoresis, and priapism. Dermatologic side effects include hair loss, photosensitivity, and maculopapular or acne-like skin reactions. Visual disturbances can include cataracts or retinopathy. Effects on the gastrointestinal system can include constipation, diarrhea, nausea, vomiting, anorexia, dyspepsia, or hypersalivation. Endocrine effects can include breast engorgement, gynecomastia, menstrual irregularities, impotence, increased libido, hyperglycemia, hypoglycemia, or hyponatremia. Hematologic reactions may include agranulocytosis, anemia, leukocytosis, leucopenia, or lymphomonocytosis. Hepatic side effects can include jaundice or impaired liver function. Respiratory manifestations may include bronchospasm, laryngospasm, or increased depth of respiration. Since the release of haloperidol, there has been one case of hyperammonemia in a 5-year-old child with citrullinemia, an inherited disorder of ammonia excretion. Haldol Decanoate may produce a local tissue reaction at the injection site.

Halstead-Reitan Neuropsychological Test Battery

Beth Springate¹ and Deborah Fein²

¹Department of Psychology, University of Connecticut, Storrs, CT, USA

²Department of Psychological Sciences, University of Connecticut, Storrs, CT, USA

Synonyms

HRB

Description

The HRB represents a fixed battery approach to neuropsychological assessment. The HRB is composed of three separate batteries: the adult battery (Halstead Neuropsychological Test Battery for Adults; ages 15+), an older children's battery (Halstead Neuropsychological Test Battery for Children; ages 9–14), and a younger children's battery (Reitan-Indiana Neuropsychological Test Battery for Children; ages 5–8). The adult battery is composed of the Category Test, Tactual Performance Test, Seashore Rhythm Test, Speech Sounds Perception Test, Finger Oscillation Test, Trail-Making Test, Aphasia Screening Test, Sensory-Perceptual Disturbances Test, Lateral Dominance Test, and Grip Strength Test. In creating the older children's battery, Reitan simplified and/or shortened the Category Test, Trail-Making Test, Tactual Performance Test, and Speech Sounds Perception Test (Reitan and Wolfson 1992a). Several of these tests were simplified by Reitan when he created the older children's battery (Horton 2008). Additional modifications were made for the younger children's battery, including addition of the Progressive Figures Test (a visual modification of the Trail-Making Test), use of an electronic finger tapper, and simplification of the Category Test, Tactual Performance Test, and Sensory-Perceptual Examination (Reitan and Wolfson 1992b). An age-appropriate Wechsler intelligence

measure, as well as a personality measure such as the Minnesota Multiphasic Personality Inventory, is also typically administered (Horton 2008).

Historical Background

Development of the HRB began in the 1940s when Dr. Ward Halstead aimed to develop a series of tests sensitive to the presence of brain damage, in contrast to the single-test assessment approaches which were prevalent at the time. In order to develop his test battery, Halstead observed brain-damaged patients in their everyday lives to discern which aspects of their behavior were different from the behavior of unimpaired individuals. Given the heterogeneity of their deficits, it was clear to Halstead that a single test would likely not be able to adequately identify and evaluate the nature of their deficits (Reitan and Wolfson 2009). Halstead ultimately developed 10 tests he considered to be sensitive to the presence of brain damage (Halstead 1947).

In a fact-driven validation procedure over the course of 15 years, Dr. Ralph Reitan utilized Halstead's original 10 tests to examine patients and blindly interpreted the results without knowledge of their histories or neurological findings. After a report was written, it was compared with an independent summary of the medical and neurological findings in order to examine inaccuracies in the neuropsychological test results. Tests were accepted or rejected solely on the basis of their accurate prediction of the presence of brain damage for thousands of patients with various types of injuries. Although Halstead's tests typically resulted in a correct conclusion about whether a patient had brain damage, conclusions regarding the nature of the damage (e.g., lateralization, type of lesion) could not be done in a highly accurate manner. Reitan experimentally evaluated additional tests for their ability to provide information about the nature of the brain damage. Three of Halstead's original 10 tests were ultimately excluded as a result of this procedure (Reitan and Wolfson 2009).

Psychometric Data

Interpretation of results from the HRB typically occurs along several different levels of analysis: level of performance, pathognomonic signs, score patterns, and right-left differences. Analysis at the level of performance involves the comparison of patients to normative standards. However, many other factors besides brain injury can impact test performance (e.g., limited education, mood disorders), and the patients' degree of decline from pre-morbid function is not taken into account. Use of composite indices generated from test results, as well as comparisons to performance on Wechsler intelligence measures, can occur at this level of interpretation. Interpretation at the level of pathognomonic signs involves examining for evidence of aphasia, agnosia, and apraxia. Limitations at this level of analysis include the reliance upon the examiner's judgment for the presence of signs, and depending on the location of their brain injury, individuals do not necessarily show signs. Score patterns are examined to determine the relative integrity of the two cerebral hemispheres and to allow for intraindividual comparisons. Finally, analysis of left-right differences involves the comparison of right and left hands on various sensory and motor tasks, although the utility of this can be limited in cases involving significant peripheral injury of the arms/hands (Sweeney et al. 2007; Horton 2008).

Screening tests, requiring only 30–45 min to administer, have also been developed in order to more quickly identify those individuals who would benefit from administration of the complete HRB battery. Results from young children (Reitan and Wolfson 2008a) indicate the brief screening tests have 92% sensitivity and 85% specificity in detecting individuals with brain damage. Results from older children (Reitan and Wolfson 2008b) indicate 92% sensitivity and 88% specificity in detecting individuals with brain damage. Reitan and Wolfson argue that many of the misclassified children had borderline scores, and recommendations to take into account additional sources of information were made. For adults, the screening tests had a sensitivity of 96% and a specificity of 82%, with

older adults more likely to be misclassified as brain injured (Reitan and Wolfson 2008c).

Clinical Uses

The HRB does have several limitations: It is unwieldy and difficult to transport, takes a relatively long time to administer and score, and is not suitable for thorough examination of patients with sensory or motor handicaps. It contains no formal memory tests, and supplemental language measures may also be needed. Few ecological validity studies of the HRB have been done, and adequate interpretation requires a high level of expertise and years of experience (Horton 2008). In addition, with modern neuroimaging methods, neuropsychologists are rarely called upon to identify the presence of brain injury and its location, although they may be asked to judge the integrity of localized cognitive functions (Lezak et al. 2004). Finally, the need to use demographic normative corrections with test scores has been raised as an issue, although Reitan and Wolfson (1995) argue the effects of brain damage may reduce/eliminate age and education effects. Most recently, Heaton et al. (2004) revised the demographic age, education, and gender-corrected norms to include normative data for Caucasians and African Americans. Finally, several authors have argued the greatest contribution of the HRB may be with its impact upon the practice of neuropsychological assessment more generally and its push to assess many different aspects of behavior and cognitive function during neuropsychological evaluations (Lezak et al. 2004; Horton 2008).

Handicaps, Behavior and Skills Schedule (HBSS)

Maretha de Jonge
Department of Psychiatry, University Medical Center, Utrecht, Netherlands

Synonyms

HBSS

Description

The Handicaps, Behavior and Skills schedule (HBS, Wing and Gould 1978) is a semi-structured, investigator-based interview schedule. It is the precursor of the Diagnostic Interview for Social and Communication Disorders (DISCO) (Wing 1999). The HBS was developed to be used for assessing autism symptoms in children with mental retardation. It was designed to elicit a detailed description of the child's skills, impairments, and behavior, in order to assist clinicians in their judgment of the level of development and special needs of a child in different domains. The HBS measures skills and deficits as shown in daily life instead of during formal intelligence tests. It provides the clinician with a profile of the child's pattern of development and behavior and its strengths and difficulties which can be used for treatment planning.

The interview is completed with parents or other caregivers and inquires about specific, easily observable aspects of behavior during the preceding month. It takes from 45 min to 2.5 h to complete, depending on the informant and the complexity of the child's behavior. The schedule consists of items covering behavioral abilities, such as social skills, language and communication, imaginative play, self-care, domestic skills, visuospatial abilities, and school work. In addition, there are items covering challenging behavior often seen in autism, such as sleep disturbance, echolalia, or stereotypic movements. The items within the developmental sections are hierarchically ordered according to the steps in normal development. A higher total score represents a higher level of development. A high total score on the part of the schedule covering specific abnormalities signifies less severe behavioral difficulties.

Historical Background

The HBS was developed in the early 1970s, by Lorna Wing and Judith Gould. It was constructed

to be used in an epidemiological study of all children under 15 years of age with intellectual disability and/or autistic characteristics in the former London Borough of Camberwell. One of the aims of the Camberwell study was to identify children with features of autism and to see if any patterns could be discovered among the clinical pictures thus found. At that time, several checklists, questionnaires, and behavior observations scales were available for the assessment of autistic individuals, but none of those was suitable for this study. Most instruments were designed to identify autism, rather than to collect detailed information about skills and difficulties necessary to investigate patterns of behavior.

Therefore, the Handicaps, Behavior and Skills schedule was constructed. The developmental and self-care items were largely based on an unpublished research interview schedule by Williams and Kushlick and on the Vineland Social Maturity Scale (Doll 1965). The behavioral items were in part derived from a previous rating scale by Wing (1969) and based on the work of DeMyer (1971), Rutter et al. (1971), and Sheridan (1969).

The schedule enabled the researchers to delineate skills, challenging behaviors, and the three specific impairments that were found to co-occur: social problems, communication deficits and repetitive activities, and a lack of imaginative play (later known as the triad of impairments; Wing and Gould 1979).

In 1990, the Elliot House Centre for Social and Communication Disorders was set up by the National Autistic Society (UK). Both children and adults with a variety of developmental disorders and cognitive abilities, ranging from profound mental retardation to superior cognitive skills, were referred to this center. The HBS, which had been designed for children with intellectual disability, did not fulfill the requirements in clinical practice. It was adapted to cover all ages and levels of ability and to record not only current behavior, but also developmental history. The adapted schedule was renamed the Diagnostic Interview for Social and Communication Disorders (DISCO).

Psychometric Data

Very few data are available on the psychometric properties of the HBS. In the original study of Wing and Gould (1978), the inter-informant reliability was investigated. Both parents and nurses/teachers of 104 children were interviewed. The mean Spearman correlation coefficient was 0.8 (ranging from 0.2 to 0.9), and the mean kappa was 0.5 (ranging from 0.1 to 0.8). In general, parents and teachers were in agreement, except for a few behavioral features for which the correlations were weak, such as echolalia, intonation, or special skills.

Age and sex were not significantly associated with the level of agreement between parents and nurses/teachers. The severity of the mental retardation and type of disability were significantly associated with level of agreement. There was better agreement for children with lower developmental levels and fewer behavior problems.

Inter-rater reliability was calculated on 20 interviews. When raw scores were collapsed into a 3-point scale, there was maximum overall agreement between the raters on 30 of the 31 sections in all children.

Internal consistency was investigated in a Dutch study with 72 children (Van Berckelaer-Onnes and van Duijn 1993). Cronbach's alpha coefficients were considered satisfactory, ranging from 0.4 to 0.7, and slightly higher when only the autistic individuals were included, except for the imagination/social play subscale.

Clinical Uses

The HBS has been adapted and reconstructed to make it suitable for clinical use with individuals of all ages and levels of ability. In addition to present functioning, it now covers also developmental history. This revised interview is named the Diagnostic Interview for Social and Communication Disorders (DISCO) (see [DISCO](#)).

Hand-Over-Hand Assistance

Brian Reichow

Child Study Center, Yale University School of Medicine, New Haven, CT, USA

Anita Zucker Center for Excellence in Early Childhood Studies, University of Florida, Gainesville, FL, USA

Synonyms

[Controlling prompt](#); [Full physical prompt](#)

Definition

Hand-over-hand assistance involves placing one's hands over an individual with autism's hands to help them complete a movement. When using hand-over-hand assistance, the adult is controlling the movements of the child's hands. For example, hand-over-hand assistance can be used to help teach a child how to wash their hands. In this

case, the adult would take the child's hands in their hands and complete all of the steps of hand washing using the child's hands; i.e., the adult would use the child's hands to turn on the water, pump the soap, scrub hands. . .dry hands. Hand-over-hand assistance, also referred to as a full physical prompt, is the most intrusive prompt that you can use, and care should be taken to ensure the adult is not exerting too much force on the child. Because it is the most restrictive prompt, it should be used sparingly when other options are not effective and systematically faded to less intrusive prompting techniques (e.g., partial physical prompts, models).

Hanen Approach

Elizabeth Spencer
College of Education and Human Ecology,
The Ohio State University, Columbus, OH, USA

Definition

The Hanen approach is an intervention approach in which parents and educators are taught to facilitate communication development in young children. The Hanen Centre has developed a number of programs designed to teach parents and educators of young children to promote communication, social skills, and literacy in everyday activities. Two specific approaches have been developed for parents of children with autism: More Than Words[®] – The Hanen Program[®] for Parents of Children on the Autism Spectrum and

TalkAbility[™] – The Hanen Program[®] for Parents of Verbal Children on the Autism Spectrum.

The Hanen approach includes seven programs, four for parents and three for early childhood educators. These programs are:

- It Takes Two to Talk[®] – The Hanen Program[®] for Parents of Children with Language Delays
- Target Word[®] – The Hanen Program[®] for Parents of Children who are Late Talkers
- More Than Words[®] – The Hanen Program[®] for Parents of Children on the Autism Spectrum
- TalkAbility[™] – The Hanen Program[®] for Parents of Verbal Children on the Autism Spectrum
- Learning Language and Loving It[™] – The Hanen Program[®] for Early Childhood Educators
- Teacher Talk[™] Training Series
- ABC and Beyond[™] – The Hanen Program[®] for Building Emergent Literacy

Historical Background

The Hanen Centre is a Canada-based nonprofit center. The first Hanen program was designed in 1975 to teach parents to take a primary role in helping their young children develop communication. This original program became *It Takes Two to Talk*. The Hanen approach now includes seven programs, four for parents and three for early childhood educators, designed to teach parents and educators of young children to promote communication, social skills, and literacy in everyday activities. Hanen programs are now offered in Canada, the United States, and other countries around the world.

Rationale or Underlying Theory

Hanen programs reflect a family-centered model of intervention based on a social-interactionist perspective of language development. The Hanen approach is based on the principles that parents should be involved in their child's intervention process and that communication should be facilitated in naturalistic contexts. Hanen

programs emphasize the critical role of parents, the importance of early intervention, and a focus on everyday routines and activities. The Hanen programs are designed to provide social support for parents in small-group interactions with other parents.

The strategies that parents are taught in *It Takes Two to Talk* are based on the responsivity hypothesis. According to this hypothesis, when parents are taught to respond to child's communication and focus on the child's interest, language input is more easily processed by the child.

The strategies that parents are taught in *More Than Words* are based on a social-pragmatic theory approach. Social communication is facilitated by structuring the environment to promote communication and by responding to the child's communication.

The strategies that parents are taught in the *TalkAbility* program are based on research on development of theory of mind. Specifically, the program emphasizes a connection between the development of language and the development of theory of mind.

Goals and Objectives

The goals of the Hanen approach are to teach parents and educators to promote communication with young children during daily routines and activities. *It Takes Two to Talk* is designed to teach parents to help their young children with language delays develop language skills. *More Than Words* is designed to teach parents to help their children with autism improve social skills, increase receptive language, and engage in interactions. *TalkAbility* is designed to teach parents to help their verbal children with autism improve social skills, participate in conversations, and understand the meaning of nonverbal cues like body language and facial expressions.

Treatment Participants

The Hanen approach is designed for parents, early childhood educators, and young children. *It Takes*

Two to Talk is designed for parents of children with a language delay who are 5 years and younger. *More Than Words* is designed for parents and their children with autism 5 years old and younger. *TalkAbility* is designed for parents and their verbal children with autism between 3 and 7 years old.

Treatment Procedures

The Hanen programs are led by Hanen-certified speech-language pathologists. Small groups of parents or educators participate in group teaching sessions and individual feedback sessions. Individual feedback sessions use videotapes of parent-child or educator-child interactions.

It Takes Two to Talk is a program for parents of children with language delay and is conducted by a Hanen-certified speech-language pathologist. The program includes a preprogram consultation, 6–8 small-group teaching sessions, and three individual visits in which the parent and the speech-language pathologist review videotapes of the parent and child interacting. *It Takes Two to Talk* is designed to teach parents to be responsive to their child. Parents are taught to respond promptly and positively when their child communicates. Parents are also taught to follow the child's lead by talking and paying attention to what the child is interested in. The focus of the program is on teaching practical strategies that parents can use in daily routines and activities. For example, parents are taught to *OWL*: observe, wait, and listen to follow their child's lead during daily routines such as meal time. *It Takes Two to Talk* also teaches parents to use strategies during play, when reading books, and with music. Parents are also taught to identify and respond to their child's individual communication ability. For example, parents of a child who is a *Communicator* learn to recognize and respond to their child's gestures and sounds.

More Than Words is an 11-week program for parents of children with autism and is conducted by a Hanen-certified speech-language pathologist. The program includes a preprogram consultation, eight small-group teaching sessions, and three

individual visits in which the parent and speech-language pathologist review videotapes of the parent and child interacting. The *More Than Words* program is designed to guide parents in adjusting the way they talk to their child with autism during daily activities. Materials include a guidebook and accompanying DVD. The 4-S acronym identifies the key elements of the approach: Say Less, Stress, Go Slow, and Show. Parents learn to simplify what they say to their children, to talk about what their child is paying attention to and stress key words, and to talk slowly and use pictures, gestures, and objects. The program is designed to teach parents to use strategies in daily routines (e.g., meals, bath time).

TalkAbility is conducted by a Hanen-certified speech-language pathologist. The program includes a preprogram consultation, small-group teaching sessions, and individual visits in which the parent and speech-language pathologist review videotapes of the parent and child interacting and videotapes of the child interacting with another child. The *TalkAbility* program is designed to teach parents to facilitate social communication and social skills with their verbal children with autism. Materials include a guidebook and accompanying DVD. The *TalkAbility* program emphasizes social communication skills like conversational turn-taking, storytelling and imaginative play, and peer relationships. In the program, parents are taught to identify their child's communication strengths and weaknesses. For example, the guidebook provides a *Conversation Checklists* for parents to use to identify the stages of conversations that their child struggles with. Parents are taught strategies to teach their child to have successful conversations. For example, for a child who has trouble initiating a conversation, a parent is taught to interpret the child's nonverbal messages (e.g., watching a peer play with a toy) and provide a verbal model (e.g., You want to play.).

Efficacy Information

Efficacy studies have been conducted on some of the Hanen programs, but empirical support is limited. In most of these studies, a quasi-experimental design was employed. Participants

in the treatment groups have been parents participating in a Hanen program. Participants in the control groups have been groups of parents on the wait list to participate in a Hanen program.

In a quasi-experimental study, parents who participated in *It Takes Two to Talk* demonstrated changes in interaction with their children including increases in responsivity and decrease in complexity of language directed at child. Children whose parents participated in *It Takes Two to Talk* demonstrated an increase in expressive language. Other studies have examined effectiveness of approaches that use procedures modified from the Hanen approach. In a quasi-experimental study, parents were taught a modified Hanen approach that emphasized target vocabulary words. Parents demonstrated a change in parental interaction and children demonstrated an increase in expressive vocabulary.

Case studies and quasi-experimental design have been used to examine the outcomes of parents and children who have participated in the *More Than Words* program. Case studies have reported an increase in parental interaction and child social interaction following participation in the *More Than Words* Program. In a quasi-experimental study, parents who participated in the *More Than Words* program had higher scores on measures of parental interaction and children had higher expressive vocabulary relative to the control group.

There are no published efficacy studies of *TalkAbility*.

Outcome Measurement

The Hanen Approach does not specify outcome measurement. Research studies that have examined *It Takes Two to Talk* have measured outcomes of parent interaction and child communication. Parent interaction has been measured using researcher-developed coding systems. Child communication has been measured using standardized measures (e.g., The Sequenced Inventory of Communication Development), researcher-developed tools, and analysis of language samples.

Research studies that have examined the *More Than Words* program have used the following tools to measure outcomes: the *Autism Diagnostic*

Observation Schedule, the *MacArthur-Bates Communicative Development Inventory*, the *Behavior Screening Questionnaire*, the *Questionnaire on Resources and Stress*, and the *Parent Feelings Questionnaire*. Researcher-developed measures have included the *Joy and Fun Assessment* and other parent report measures. Outcomes also have been measured using analysis of parent-child interactions, spontaneous language samples, researcher-child interactions, and child social initiations.

Qualifications of Treatment Providers

For the parent-teaching programs, including *It Takes Two to Talk*, *More Than Words*, and *TalkAbility* programs, qualified treatment providers are speech-language pathologists who have received certification from the Hanen Centre. Certification in *It Takes Two to Talk* requires participation in a 3-day workshop led by a Hanen Instructor. Certification in the *It Takes Two to Talk* program is a prerequisite for certification in all other programs. Certification in *More Than Words* requires participation in another 3-day workshop led by a Hanen Instructor. Certification in *TalkAbility* requires certification in both *It Takes Two to Talk* and *More Than Words* and participation in a 2-day workshop led by a Hanen Instructor.

Early childhood professionals can become qualified treatment providers for the Learning Language and Loving It and ABC and Beyond programs.

internship at St. Elizabeths Hospital in Washington, DC, after which she accepted a position as assistant professor at Douglass College, Rutgers, The State University of New Jersey. Dr. Harris has been at Rutgers ever since, retiring in 2007.

Major Appointments (Institution, Location, Dates)

- Douglass College, Rutgers, The State University of New Jersey: 1969–1979. Assistant and associate professor
- Graduate School of Applied and Professional Psychology, Department of Clinical Psychology and Department of Psychology, Faculty of Arts and Sciences, Rutgers, The State University of New Jersey: 1979–2007. Professor I and professor II
- Graduate School of Applied and Professional Psychology, Rutgers, The State University of New Jersey: 1992–1993, acting dean; 1993–2001, dean
- Board of Governors Distinguished Service Professor, Rutgers, The State University of New Jersey: 2003–2007
- Board of Governors Distinguished Service Professor Emerita, Rutgers, The State University of New Jersey: 2007
- Douglass Developmental Disabilities Center, Rutgers, The State University of New Jersey 1972–2007: Founder and executive director

Major Honors and Awards

She is the recipient of numerous awards for distinguished service and contributions to science including the Daniel Gorenstein Memorial Award, the President's Award for Research in Service to New Jersey, the Anne Klein Advocate Award, and the Distinguished Alumni Award, SUNY Buffalo.

Harris, Sandra

Michael D. Powers
The Center for Children with Special Needs,
Glastonbury, CT, USA

Name and Degrees

Sandra L. Harris (1943–) received her BA from the University of Maryland and PhD in clinical psychology from the State University of New York at Buffalo. She completed her clinical

Landmark Clinical, Scientific, and Professional Contributions

Dr. Harris' scientific and clinical interests have been at the forefront of the evolution of

evidence-based treatment for those with autism and their families for over 40 years. From an early interest in teaching language and the generalizability of teaching strategies to families to treatment of core behavioral and social deficits of autism, through research on the effect of autism on parents, grandparents, and siblings, and to demonstrating the effectiveness and sustainability of intensive early behavioral intervention, her work with colleagues and students has been both robust and pragmatic, emphasizing the development of new science but also the training of new professionals in those endeavors. Dr. Harris established one of the first behavioral treatment centers for children with autism in the United States at the Douglass Developmental Disabilities Center and, in so doing, created both a nationally recognized center of excellence for educating individuals with autism across the life span and also a training facility for a generation of psychologists, teachers, and other health-care professionals working in the field.

Short Biography

As a clinical psychologist in the best tradition of the scientist-practitioner model and as an educator, Dr. Harris has mentored a generation of leaders in the field of evidence-based behavioral treatment of those with autism spectrum disorders. While initially devoting her efforts for many years to research and teaching in the graduate program in clinical psychology at Rutgers and simultaneously serving as executive director of the Douglass Developmental Disabilities Center, Dr. Harris became the third dean of the Graduate School of Applied and Professional Psychology (GSAPP), the nation's first university-based school of professional psychology, in the early 1990s. For a period of nearly 10 years, she oversaw a substantial expansion of GSAPP's training, clinical, and community-based programs, in the process of helping to reshape the mission of this flagship program. By honoring her as the Board of Governors distinguished service professor in 2003, the Rutgers community recognized her contributions to research and service

to the children and families of New Jersey and beyond. While she retired as professor emerita in 2007, Dr. Harris continued to serve as executive director of the Douglass Developmental Disabilities Center and to mentor new professionals for nearly 10 additional years, retiring recently.

Hate Crimes/Victimization

Mark Sherry

Department of Sociology and Anthropology,
University of Toledo, Toledo, OH, USA

Definition

Many people with autism experience abuse, maltreatment, and other forms of victimization including hate crimes. Experiences of victimization can take many forms, including physical, sexual, emotional, medical, and financial abuse. Physical abuse can include hitting, slapping, and pushing; sexual abuse can involve unwanted touching, sexual contact, or rape; emotional abuse can include bullying, threatening, and intimidating a person; medical abuse can involve overmedicating a person or denying them appropriate medications; and financial abuse involves wrongfully using someone else's finances. These forms of abuse are sometimes called maltreatment, bullying, or neglect. As well as the forms of abuse listed above, neurodiverse people may be subjected to disability hate crimes. Disability hate crimes involve the deliberate targeting of an individual because of his or her disability.

Historical Background

Studies of abuse and victimization have been conducted for decades, consistently indicating that there is an unacceptably high rate of victimization of people across the autistic spectrum in terms of abuse, harassment, bullying, and other forms of victimization. However, the actual estimations of the overall rate differ greatly. These different prevalence rates possibly reflect different methodologies: some studies ask caregivers, others ask parents, and others ask neurodiverse people. The size of the sample (i.e., the number of people questioned in the survey) also is a major factor in terms of the generalizability of the study – smaller samples tend to mean that the

results cannot automatically be assumed to apply to different groups across a broad range of social and cultural contexts.

One study of the experiences of 156 children with autism asked caregivers to indicate whether their children with autism had been abused (Mandell et al. 2005). These caregivers reported that 18.5% of children with autism had been physically abused and 16.6% had been sexually abused. Such abuse frequently resulted in self-harming strategies, such as suicide attempts, by the victims of abuse. Other effects included sexually acting out, running away from home, and psychiatric hospitalization. A similar study, which asked parents of people with Asperger's syndrome whether their child had been abused, reported that 100% of the children had been victimized, on average 1.25 times per week, but for 23% of the children, such victimization occurred on average twice or three times per week (Konstantareas 2005).

In the United Kingdom, the National Autistic Society has reported that 56% of people with autistic spectrum disorder have been bullied or harassed as adults, a figure which rises to 70% for those people with autistic spectrum disorder who live alone (Rosenblatt 2008). This organization wrote a response to the UK Government's "Anti-social behavior: policy and procedure" document which contained one story about a person who was given the pseudonym of Matthew. The document explained that Matthew had experienced verbal abuse, graffiti on his home, and was hospitalized after being physically assaulted within his own home. Matthew's autistic spectrum disorder made it harder to communicate effectively with police. He lacked support workers or family who could help him in lodging such criminal complaints (The National Autistic Society 2009). This problem raises another issue: the importance of support programs that assist disabled people in accessing the criminal justice system. And there is obviously a need to raise awareness of the problems that such barriers exist in the first place.

People with Asperger's syndrome have been called "perfect targets" for bullying and

victimization (Heinrichs and Myles 2003). For instance, when students with Asperger's syndrome are constantly reminded that they do not "fit in" and that their social, academic, or communication skills make them somehow "abnormal," they become not only socially marked but socially isolated and victimized as well. When a potential target is seen as socially isolated and having little peer support, a bully might assume that there will be little or no consequences for their actions. Additionally, many people with Asperger's syndrome are unable to predict the social behavior of others, making it even more difficult for them to avoid potential setups for violence, intimidation, or bullying.

Current Knowledge

There have been some suggestions that certain behaviors associated with autism and with the processes used to interview victims of crimes reduce the likelihood of sexual abuse against an autistic person being recognized. For instance, one author suggests that "because of the use of lengthy, one-time interviews and the need for sustained reciprocity and verbal exchanges," autistic people may face extreme barriers in interviews with law enforcement personnel (Edelson 2010). Additionally, the behaviors which an autistic person might demonstrate in response to sexual abuse may be misattributed to autism rather than a sex crime. Nevertheless, psychological evaluations of people across the autistic spectrum who have experienced various types of trauma, abuse, and harassment consistently indicate that they have lower self-esteem and higher rates of depression and anxiety than those who have not been victimized (Brownlie et al. 2007; Mandell et al. 2005; Shtayermman 2007).

A number of studies suggest that the vast majority of perpetrators of abuse are male and are known to the victim (National Center for Injury Prevention and Control 1998). Perpetrators of abuse include caregivers, family members, other people with disabilities, health-care providers, and acquaintances. The fact that many

people with disabilities have a number of caregivers in their lives, whose work often involves rather intimate tasks, may be one of the factors which puts them at increased risk of abuse. Social and personal boundaries are often at risk of being blurred in the provision of personal assistance (Saxon et al. 2001; Saxton et al. 2006).

The following cases involving crimes against people with autism gained national attention in the media. They involve two US cases: threats to burn an autistic boy's home and the deliberate hitting of an autistic boy in a T-ball game. In Seattle in July 2008, Mark Joe Levison was charged with malicious harassment after threatening to burn the home of an autistic child. In July 2008, he is alleged to have told the child's mother "Keep your fucking son in the house or the backyard like a dog. If you don't I'll burn the (child's bedroom) down" (Jones 2008). The family had only moved into the house 2 weeks earlier and the child's mother, Acquinnette Engen, said "I was terrified." According to police, Levison, 48, also said "I pay \$1,000 a month rent and shouldn't have to see that idiot spinning around and staring at my house" (Pulkkinen 2008). Levison was again arrested a few months later for similar behavior. One report indicated that he had repeatedly threatened to burn down the home, had also taken to imitating the autistic child, and had challenged the child's father to a fight. He pleaded guilty in November 2008 to one count of malicious harassment, a felony, and one count of attempted malicious harassment, a misdemeanor (Sherry 2010). Levison was sentenced to nearly 4 months in jail, as well as a 1-year suspended sentence that could be imposed if he violated the conditions of his release during the next 2 years. Levison was also ordered to undergo substance abuse treatment and anger management classes; he was a self-described "alcoholic" and told the judge "When I'm sober, I would never say words like that" (Seattle Times Staff 2008).

The case of Mark Reed Downs, a 27-year-old T-ball coach from Philadelphia, illustrates the ways in which people with autism can be attacked in social situations. (T-ball is a children's version of baseball). Downs was coaching a children's

team in 2005 when he offered one of his players \$25 to hit Harry Bowers, Jr., an 11-year-old autistic boy on their own team, in the head with a baseball during warm-ups so that he would be unable to play that day. After speaking to the coach, the player threw a ball which bounced and then hit the disabled child in the groin with a pitch. Bowers ran off crying to his mother. She sent him back out to practice and the other child hit him again, this time in the ear. Bowers was unable to play in the game and was taken to the Uniontown Hospital. Bowers was targeted because his autism meant that he was not a great player, and every player is required to play three innings unless they are injured. The boy who threw the balls, Keith Reese, Jr., was one of the better pitchers in their team and the team was in the play-offs (finals) that day. He testified in court that after he had struck Bowers on the first occasion, "He (Downs) told me to go out there and hit him harder. So I went out there and hit him in the ear." Reese, Jr., testified that he did not receive the \$25 from Downs. Downs was convicted of criminal solicitation to commit simple assault and corruption of minors but was found not guilty of the more serious charge of criminal solicitation to commit aggravated assault, and the jury could not reach agreement on whether his actions constituted reckless endangerment. Downs was sentenced to 1–6 years in prison but was granted bond while appealing to the state Superior Court (Sherry 2010).

Awareness of disability hate crimes, a particular form of victimization, is growing internationally (Sherry 1999, 2000a, b, 2002, 2003, 2004, 2010). In these crimes, the perpetrator targets a person because of their disability identity. They are called "hate crimes" or "bias crimes," depending on the particular local legislation. Perpetrators often receive additional sentencing for the hate crime, as well as the original crime, because hate crimes not only affect the individual but also the whole community to which that person belongs. Hate crimes send a message of intolerance that might mean people in the group consider a particular place unsafe and a "no go zone," so the perpetrator is punished for that effect of their actions as well.

Future Directions

The future direction for dealing with and preventing abuse, maltreatment, and other forms of victimization involves the development of a multidimensional response. One author recommends six different areas which could be addressed to eliminate bullying of children with Asperger's syndrome: empowering victims, empowering bystanders, empowering teachers, understanding bullies, empowering parents, and empowering schools (Dublin 2007). Presumably, the responses for adults would be somewhat different, given that they are not in school. Some of the more general responses which have (Sherry 1999, 2000a, b, 2002, 2003, 2004, 2010) been developed to prevent abuse include training programs for both potential victims and caregivers to increase awareness of abuse issues; sex education programs which emphasize choice-making, personal rights, and assertiveness training; and staff screening programs involving improved reference and police checks to weed out convicted sex offenders from caregiving positions (Sobsey 1994). It is essential that child protection workers, law enforcement personnel, and educators (particularly in special education settings) be provided with sufficient training in order to appropriately respond to cases of disability abuse.

Unfortunately, many child protection workers lack knowledge about disability issues. This lack of confidence dealing with disability issues has led to the situation where disabled children are overrepresented among victims of abuse but underrepresented among the caseloads of child protection workers (Orellove et al. 2000). As a result, disabled victims of abuse often experience significant difficulty in accessing appropriate services. Many professionals also report a lack of training in dealing with abuse histories of male clients, which may compound these problems (Lab et al. 2000).

Another specific challenge for investigators may be the use of assisted communication by some people with autism. Assisted communication may involve the use of symbols, pointing devices, computer aids, a communication partner, word prediction software, and many other

individualized approaches. These assisted communication tools are necessary because up to 25% of people with autism have communication impairments (Howlin 2006). However, many law enforcement officers and court systems are unfamiliar with these communication techniques, creating an additional barrier for victims who seek redress through the judicial system.

Abuse, harassment, vilification, and maltreatment are unfortunately common experiences for people with autism. They can have devastating and lifelong effects on self-esteem and leave a person struggling with depression and anxiety. Awareness of this problem is growing within the community and within the criminal justice system, as more victims come forward and discuss their experiences. However, many cases are not reported, for fear of retaliation or for fear that the victim will not be believed. Also, there are challenges associated with limited awareness about assisted communication devices within the criminal justice system. There is a definite need for more advocacy, support, and awareness of this problem.

Institute of Technology, Central Islip, NY, USA

Definition

The Higher Education Opportunity Act of 2008 is also known as Public Law 110–135. It is the latest reauthorization of the Higher Education Act of

1965 (Pub. L. No. 89–329), originally signed into law by President Lyndon Johnson on November 8, 1965. The Higher Education Opportunity Act of 2008 is important for individuals with a diagnosis of autism or an autism spectrum disorder because it creates new legislative requirements for access to postsecondary education for individuals with an intellectual disability.

Historical Background

The real importance of the passage of the Higher Education Opportunity Act of 2008 (HEOA) for individuals with a diagnosis on the autism spectrum is in its legislative mandates for higher educational opportunities for individuals with an intellectual disability. The original Higher Education Act (HEA) of 1965 does not specifically provide for educational opportunities for individuals with a disability. Nevertheless, the history of the Higher Education Act of 1965 and its subsequent amendments and reauthorizations provides a context for understanding the new legislative provisions in the HEOA of 2008. While the Education Act of 1965 and its subsequent revisions has provided for federal support for many aspects of higher education in the United States, the most extensive impact of the legislation has come from Title IV of the Act which provided for direct federal financial aid to students pursuing higher education as well as federally subsidized loans for these students. The limits on access to this financial aid is central to the new legislative mandates in HEOA of 2008 which support access to higher education for individuals with an intellectual disability. This section will provide a brief historical context to the original passing of the Higher Education Act and examine the major developments in the legislation in its nine subsequent reauthorizations since 1965.

In the United States, the establishment of institutes of higher education has always been a private or state responsibility. The United States has never established a national university. The federal role in higher education has been via certain federal laws and regulations and limited, targeted federal aid. The early aspect of direct federal aid to

higher education came via legislation that mandated that certain lands be set aside for the establishment of institutes of higher education. The first provision for this was as part of the Northwest Territories Act of 1787 and then similar provisions where the central purpose of the Morrill Acts of 1862 and 1890 creating the so-called Land Grant Colleges. Probably, the most significant foray of the federal government into support for higher education was the Servicemen's Readjustment Act of 1944, more commonly known as the "GI Bill." The GI Bill provided financial support to honorably discharged veterans for from 1 to 4 years of study in an institute of higher education. Prior to the passage of the Higher Education Act, congress passed the National Defense Education Act in 1958. This Act used a needs-based formula to provide low-interest loans to college students studying science, math, or foreign languages. Students who became teachers had an option to have their loan forgiven.

As part of President Lyndon Johnson's War on Poverty, he commissioned a taskforce on higher education and the role of the federal government in student aid. The recommendations from this taskforce ultimately become the major provisions of the Higher Education Act (HEA). The HEA was sponsored in congress by Wayne Morse in the senate and by Edith Green in the house, both representing the state of Oregon. The Act was signed into law by President Lyndon Johnson on November 8, 1965, at his alma mater, the Southwest Texas State College (now known as Texas State University). The Act had seven major sections identified as Title I–Title VII. Title I of the Act provided for grants to strengthen community service projects in particular those addressing such problems as poverty, housing, transportation, and youth opportunities. Title II provided grants for the expansion of college library collections as well as for an increase in the education and training of college librarians. Title III provided for aid to developing institutions with its aim primarily to support the growth of traditional African-American colleges. Technical and 2-year colleges could also receive support under Title III. Title IV is probably the best known aspect of the HEA and will be discussed in more detail below.

Title IV provided for both direct federal financial aid as well as federally insured loans for eligible college students enrolled full-time. Title V established a Teacher Corps for the development of better teacher education. Title V is later moved to a reauthorization of the Elementary and Secondary Education Act. Title VI established grants for the use of technology in the improvement of undergraduate education. Title VII afforded institutes of higher education with funding for new construction. Title VII amended and incorporated the Higher Education Facilities Act of 1963 into the HEA.

Title IV has been the most influential aspect of the HEA having substantially increased access to higher education for a large segment of American society. Title IV of the HEA of 1965 had four parts labeled A–D. Part A itself and two main provisions were the first created Educational Opportunity Grants, which are now known as Supplemental Educational Opportunity Grants. The Educational Opportunity Grants were funneled through the states to the institutes of higher education who could then distribute them to students in need based on their own criteria. The second provision in Part A of Title IV incorporated an existing program, Upward Bound, with a new program called Talent Search in order to encourage college attendance among disadvantaged youth. Part B of Title IV established Guaranteed Students Loans, loans that would be funded by private lenders but backed by federal guarantees. There have been numerous changes in this program over the years, but the essential features of the original legislation still exist: loans are made directly to student families from private lenders, but the lenders have the promise of payment from the federal government if the recipient defaulted on the loan. In addition, based on need, the loan recipient may have some of her or his interest subsidized while attending school.

A third aspect of Title IV was the incorporation of the Federal Work Study Program into the HEA, which was authorized in Part C of the Title. A Federal Work Study Program had already been started as part of the War on Poverty, but would now be moved to the Department of

Education from the Office of Economic Opportunity. Federal Work Study is funded by the institute of higher education with matching funds from the federal government. The final provision under Title IV of the HEA was to move the National Defense Student Loan (NDSL) Program from the Office of Economic Opportunity to Department of Education. The NDSL program is now known as the Perkins Student Loan program. It is a direct loan program and is funded by both the federal government and the individual institutions of higher education. It provides low-interest loans to financially needy undergraduate, graduate, and professional students.

Current Knowledge

The Higher Education Opportunity Act (HEOA) of 2008 (Public Law 110–135) is the ninth reauthorization of the original 1965 law (Pub. L. No. 89–329). The 2008 law was passed on July 31, 2008, and signed into law on August 14, 2008. The reauthorization was 5 years late and completed after congress passed 14 extensions of the statutory deadline. Originally, the 1998 reauthorization only extended until September 30, 2003.

While the reauthorization addresses literally hundreds of different provisions within the law, the essential aspects of the new law that have a new and unique impact for individuals with a diagnosis on the autism spectrum are the provisions related to postsecondary education for individuals with an intellectual disability. Thus, this section will primarily explicate the new rights and mandates concerning postsecondary education for individuals with an intellectual disability. The end of the section will briefly overview the other main provisions of the new law.

There are four main features of the HEOA of 2008 that address students with an intellectual disability. The law provides for a competitive federal grant program for institutes of higher education to create model comprehensive postsecondary transition programs for students with an intellectual disability. HEOA also provides authorization for the creation of two centers to support the development of transition programs. One initiative is to create a National Center for

Information and Technical Support for Postsecondary Students with Disabilities. The second is to create a Coordinating Center for institutes of higher learning offering postsecondary transition programs for individuals with an intellectual disability. And finally, the law opens the eligibility for receiving Pell Grants, Federal Supplemental Education Opportunity Grants, and Federal Work Study for students with an intellectual disability. Importantly, for students enrolled in an approved comprehensive postsecondary transition program, the law modifies the requirements for full-time matriculation in a degree-granting program and for demonstrating satisfactory academic progress.

The Higher Education Opportunity Act of 2008 expands access to higher education for students with an intellectual disability. Probably, the most substantial change in the law for students with an intellectual disability is modifications to Title IV of the law addressing student financial aid. Prior to this, it was difficult for a student with an intellectual disability to be eligible for any type of federal financial aid because they often lacked a regular high school diploma (or General Educational Development equivalent). Even if they did meet the diploma requirement, they often failed the Title IV “ability to benefit” test, based on satisfactory academic progress as a full-time student in a degree-granting program. Changes to Title IV give the secretary of education broad authority to waive restrictions on eligibility for federal financial aid for students with an intellectual disability if they meet two general criteria. The student must be enrolled in an approved comprehensive transition program at an institution of higher education, and they must maintain satisfactory progress as determined by the institution.

Title VII (Part D, Section 760) of the HEOA defines the criteria for a comprehensive transition and postsecondary program for students with intellectual disabilities as well as defining the term “a student with an intellectual disability.” The law identifies a comprehensive postsecondary transition program as a degree, certificate, or nondegree program offered by an institution of higher education that is designed to support students with an intellectual disability

who are seeking to continue academic, career and technical, and independent living instruction in order to prepare for gainful employment; the program includes an advising and curriculum structure and requires students to participate on not less than a half-time basis, as determined by the institution and focusing on academic components. The academic components must include regular involvement with nondisabled individuals via one or more of the following: regular enrollment in credit-bearing courses, auditing or participating in credit-bearing courses, enrollment in noncredit-bearing or nondegree courses, or participation in internships or work-based training.

The change in Title VII defines the meaning of the term a “student with an intellectual disability.” Specifically, the law indicates that such a student is a student with mental retardation or a cognitive impairment, characterized by significant limitation in intellectual and cognitive functioning, and adaptive behavior as expressed in conceptual, social, and practical adaptive skills. In addition, a student with an intellectual disability is a student who is currently or formally eligible for a free appropriate public education (FAPE) under the Individuals with Disabilities Education Act (IDEA).

Subpart of 2 of Part D of Title VII of the HEOA creates the authorization of model comprehensive transition and postsecondary programs for students with intellectual disabilities. On a competitive basis, institutes of higher education will be able to apply for federal matching grants to support comprehensive transition programs. The grants, once awarded, will last 5 years. The first set of grants was awarded in October of 2010 to 27 institutes of higher learning. The list of all grantees is available via the National Coordinating Center which is housed at the Institute for Community Inclusion at the University of Massachusetts Boston (<http://www.thinkcollege.net/tpsid-coordinating-center>). The main criteria for institutes of higher education receiving funding is as follows: The program must serve students with an intellectual disability; it must provide for the inclusion of students with an intellectual disability with the regular academic and extracurricular activities of the institution; it must use a person-centered planning approach; and it must provide a focus on academic enrichment, socialization,

independent living skills, and integrated work experiences that lead to gainful employment.

In October of 2010, an award was also made to establish a National Coordinating Center for institutions of higher education offering inclusive comprehensive postsecondary transition programs for students with intellectual disabilities. This National Coordinating Center is housed at the Institute for Community Inclusion at the University of Massachusetts Boston (<http://www.thinkcollege.net/tpsid-coordinating-center>). The HEOA stipulates several key responsibilities for the National Coordinating Center. First, it must provide technical assistance for the development, evaluation, and improvement of grantee transition programs. Secondly, it should assist in developing the standards and measurable competencies for the awarding of a meaningful credential by the comprehensive postsecondary transition programs. In establishing a meaningful credential, the Coordinating Center needs to work with the transition programs in identifying the necessary programmatic components for these programs, how student progress should be evaluated, and what should determine student eligibility.

The law also calls for the creation of a National Center for Information and Technical Support for Postsecondary Students with Disabilities (National Center). As of 2011, no award for the creation of such a center had been made. The law envisions the National Center as providing technical assistance to two primary constituencies: students and their families and institutions of higher education. The law indicates that the National Center would provide information and technical assistance to individuals with a disability and their families both while they are still receiving secondary education and while they are participating in some type of postsecondary education or transition program. Included in this is a mandate for support to Individualized Education Program Teams, who are mandated to provide transition planning for students in secondary education by the Individuals with Disabilities Education Act. The law calls for the National Center to provide assistance to administrators, staff, and faculty of institutes of higher education to better recruit and retain students with a disability. Specifically, the law encourages the center to collect and disseminate proven

best-practices models for transitioning and supporting students with a disability in postsecondary education. It also calls on the National Center to provide training modules and tutorials for administrators, staff, and faculty on the best practices of supporting and retaining students with disabilities in postsecondary education.

The reauthorization of the Higher Education and Opportunities Act of 2008 does provide numerous other changes in the law, in addition to those that directly address students with an intellectual disability. The variety of changes are too numerous to elaborate on all of them here. The most important changes are summarized briefly below.

One major area of changes in the HEOA of 2008 revolves around greater transparency and reporting requirements on college costs. There are several components of the law that create new requirements for institutes of higher learning to calculate, publish, and report to the department of education accurate estimates of the net cost of attending school at their institution. In addition to the financial aid changes specific to individuals with an intellectual disability described above, the law makes several other important changes to federal financial aid law. Concerning the Pell Grant, the maximum award is increased and it is made available to students year-round (in the past, it was not available for summer sessions) in order to encourage a shorter time to degree in more schools. A major change in student eligibility for financial aid is a provision that permits institutes of higher education to register students who are also dually (or concurrently) enrolled in secondary education. The provision may also provide significant new opportunities for students with an intellectual disability. In addition, the law calls for simplifying and streamlining the federal financial aid process, including fewer and more understandable questions on the Free Application for Federal Student Aid (FAFSA).

Future Directions

The Higher Education Opportunity Act (HEOA) of 2008 (PL 110–135) was signed into law by President George W. Bush on August 14, 2008. This reauthorization of the original 1965 law opened up

dramatically new opportunities for individuals with an intellectual disability to participate in higher education. As of October of 2008, the U.S. Department of Education had funded 27 model “comprehensive transition and postsecondary programs for individuals with an intellectual disability” at both 2- and 4-year institutes of higher education throughout the United States. In addition, the Institute for Community Inclusion at the University of Massachusetts Boston received funding to establish the National Coordinating Center to support the 27 initial model programs and any other programs that might develop.

The mandate for the National Coordinating Center involves the development of national standards for the provisions of education via the comprehensive transition programs, qualitative and quantitative measures for student outcomes on program strengths, and the criteria necessary for establishing a meaningful credential. It can be expected that as these requirements are defined and solidified, more institutions of higher education will become involved in the provision of educational services to individuals with an intellectual disability.

The law calls for the creation of a National Center for Information and Technical Support for Postsecondary Students with Disabilities. As of 2011, no grant had been awarded to create such a center. It is expected that the Department of Education will create such a center and that this center will become an important advocate to individuals with an intellectual disability, and their families, seeking to continue their education beyond secondary school. Then mandate for the National Center also calls for it to be a resource for Independent Education Program Teams doing IDEA-mandated transition planning for students in secondary schools. Such a national resource of information and technical assistance should greatly increase the incidence of postsecondary education being part of the formal IEP transition plans for students with an intellectual disability.

Healthcare Transition for Individuals with Autism

Dorothea A. Iannuzzi
 Division of Academic Pediatrics, Autism
 Intervention Research Network on Physical
 Health (AIR-P), Autism Treatment Network
 (ATN), Mass General Hospital for Children,
 Boston, MA, USA

Definition

Healthcare transition for individuals with ASD is defined as the transition from pediatric to adult healthcare systems.

Historical Background

The access to and provision of quality healthcare for individuals with disabilities including autism spectrum disorder (ASD) has been identified as a significant public health issue (Bruder et al. 2012). During the period of transition from pediatric care to adult healthcare for young adults with ASD, the gap in access to high-quality patient-centered care widens further (Cooley 2013; Lotstein et al. 2008). Transition age is generally defined as occurring between the ages of 14 and 17 years, up to the age of 22 years (AAP et al. 2011). In addition, compared to youth with other disabilities, youth and young adults with ASD are more likely to require specialty care for common comorbidities such as epilepsy, gastrointestinal problems including inflammatory bowel disease (IBD), and anxiety and depression, as well as respiratory, food, and skin allergies (AAP et al. 2011).

Many obstacles can interfere with a smooth healthcare transition for TAY with ASD. The possible roadblocks include the attitudes of stakeholders; age limits in pediatric practices; complexity of health conditions; lack of insurance reimbursement for management of medical complexity often associated with transition age youth (TAY) with ASD; and, most importantly, the scarcity of competent educated healthcare providers prepared to meet the needs of this ever-growing patient demographic (Oswald et al. 2013).

Individuals with ASD have higher rates of healthcare utilization (Croen 2006; Kogan et al. 2008; Warfield and Gulley 2006; Liptak 2006), an increased burden of unmet healthcare needs (Newacheck and Kim 2005), and decreased satisfaction with the medical care received (Leslie and Martin 2007; Souders 2002). These data further support the imperative for improvement in access to quality healthcare services for individuals with ASD across the life span and especially during the period of transition from pediatric to adult healthcare (Iannuzzi et al. 2018). Many medical comorbidities can first present during the adolescent years, adding to the challenges of meeting the medical needs of this patient population (Bauman 2010).

In addition, access to developmentally appropriate quality healthcare for TAY with ASD is

extremely limited due to a critical shortage of primary care providers, including physicians and advanced practice nurses, willing to accept TAY with ASD into their adult primary care practices (Warfield et al. 2015). Studies addressing the scarcity of primary care providers have suggested that the lack of providers for this population may be a result of the lack of content, including an experiential component, focused on the healthcare needs of individuals with ASD and other developmental disabilities within health professional education programs (Bruder et al. 2012; Patel and O'Hare 2010).

Current Knowledge

Many TAY with ASD present with complex medical, behavioral, and sensory processing challenges. For example, some studies have described a prevalence of up to 80% for sleep disorders in individuals with ASD, as compared to the rate of 30% for individuals without ASD (Bauman 2010; Malow et al. 2012). Seizure disorders can occur in up to 35% of individuals with ASD, and about 60% of patients with ASD have abnormal electroencephalograms (EEGs) (Bauman 2010). The true prevalence of gastrointestinal disorders (GI) in individuals with ASD is not known; however, current estimates range anywhere from 9% to 70% (Buie et al. 2010).

Individuals with ASD can also have a hypersensitivity to auditory, visual, and tactile stimuli. These sensory challenges can be especially difficult to manage in a medical setting, where an individual may be exposed to novel smells, sounds, lighting, and medical staff that are unfamiliar (Scarpinato et al. 2010). Many individuals with ASD, including TAY, can have difficulties in overly stimulating environments like the environments found in most healthcare settings (Aylott 2010). These stimuli may result in hyper-arousal and maladaptive behavior, which can often be minimized by accommodating an individual's sensory profile and any specific sensory sensitivity they may have. Having some understanding and appreciation of the significance of these sensory processing challenges before a medical procedure or physical exam can greatly reduce the

level of distress for the patient, caregiver, and providers.

A healthcare professional may misinterpret maladaptive behaviors and not understand that these maladaptive behaviors can be a manifestation of pain. This misunderstanding can lead to serious errors in assessment and treatment (Iannuzzi et al. 2014). Assessment of discomfort can be particularly difficult in nonverbal patients with autism; pain is often communicated through maladaptive behavior (Kopecky et al. 2013). It is critical for clinicians to specifically ask the individual with ASD or their parent, guardian, or caretaker about sensory sensitivities and triggers, preferred communication methods, and, most importantly, how the individual communicates that they are in distress or pain. These are questions that most clinicians are not trained to ask and can be crucial in assessment and the development of a treatment plan that is individualized to the unique comprehensive needs of an individual with ASD presenting for care.

A clinician in the position of providing healthcare in either an emergent or primary care setting needs to understand that, at times, maladaptive behavior can also be a red flag, signaling the presence of an underlying medical issue. Lack of knowledge about the connection between aberrant behavior and pain is an issue that can lead to misdiagnosis and suboptimal medical care (Buie et al. 2010). Likewise, self-injurious or aggressive behavior exhibited by an individual with autism presenting for emergent care may represent an underlying medical issue. Thus, it is incumbent upon primary care and emergency clinicians to first investigate the possibility of an underlying medical condition that may explain aberrant behaviors (Iannuzzi et al. 2014). This is especially true for nonverbal individuals whose only means of communicating physical pain or distress is to exhibit maladaptive behaviors.

Future Directions

The current healthcare workforce, including physicians and advanced practice nurses, is simply not equipped or prepared to meet the medical

needs of adults with ASD (McDougle 2013). The need for a clinically competent healthcare workforce that is able to meet the healthcare needs of TAY with ASD will continue to increase as more young adults with ASD age out of pediatric healthcare practices. In order for healthcare professionals to develop competencies, a curriculum that is focused on the unique care needs of this patient population must be embedded into existing healthcare professional educational programs. Since individuals with ASD are growing older, are living longer, and develop many of the health issues and concerns of the typical aging population, their medical needs will increase in scope and severity (Drum et al. 2009; Henry et al. 2011; Smith et al. 2010). Because individuals with ASD across the life span can present in any healthcare setting, all healthcare providers, need to be prepared to meet the healthcare needs of this growing patient population (Smeltzer et al. 2014).

Definition

Hearing is one of our five senses. The ability to hear is contingent upon the ability to perceive vibrations in air molecules that enter the auditory system through the outer ear. This energy is transmitted through the middle ear and inner ear, ending in the temporal lobe of the brain where it is ultimately perceived. The ability to hear is a critical component to the reception and comprehension of speech. Individuals with autism spectrum disorders can have impairment in their ability to hear, but more systematic research needs to be completed regarding hearing sensitivity in this population.

Heller, Theodore

Alexander Westphal
Division of Law and Psychiatry, Yale Child Study
Center, Yale School of Medicine, New Haven,
CT, USA

Name and Degrees

Theodor Heller, Ph.D.

Landmark Clinical, Scientific, and Professional Contributions

Heller was a founding figure in special education. He also first described a disorder he termed

dementia infantilis, currently called childhood disintegrative disorder. In addition, he formed an institute for the treatment and education of children with special needs with international draw.

Short Biography

Theodor Heller was born June 9, 1869, in Vienna, Austria. His father, Simon Heller, was the director of an institute for the blind, and Heller spent much of his childhood at the institute. During school, he worked as a reader for blind people, including the philosopher Hitschmann, and through this became interested in philosophy. He went to University of Leipzig to study under Wilhelm Wundt, an important figure in modern psychology. Heller's area of concentration was the psychology of blindness, and his thesis, *Studien zur Blinden-Psychologie*, was submitted in 1894. He also explored a number of other topics including the psychology of acoustic and haptic perception. During this time, he attended lectures on medicine and the brain also and became very interested in the education of children with intellectual and developmental disabilities (special education). Shortly afterward, he started an institute for handicapped children together with his father and Richard Freiherr von Krafft-Ebing (a psychiatrist and author of *Psychopathia Sexualis*) at a property he had inherited at Grinzing in the Döbling district of Vienna. The institute started with two children as patients, but would ultimately serve 40 children at a time, many from outside of Austria. Many of the children came from wealthy families, but Heller used the proceeds to fund places for children from less privileged backgrounds. The institute included individualized treatment as well as social and academic education.

Heller was a pioneer of special education. He published works on the topic, including *Grundriß der Heilpädagogik* (*Groundwork for Special Education*) in 1904, *Pädagogische Therapie* (*Educational Therapy*) in 1914, and *Die Heilpädagogik in der Gegenwart und Zukunft* (*Special Education in the Present and Future*) in 1922. Heller also wrote about children who

underwent a sudden and catastrophic regression of their adaptive function, including sociability and language, coupled with the onset of stereotyped behaviors (all defining characteristics of autism) after a period of normal development. He termed this *dementia infantilis*, and its essential features are captured by the current diagnostic concept *childhood disintegrative disorder*, despite radical shifts in diagnostic frameworks and treatment approaches, marking the clarity of Heller's observation.

In his first publication on the topic, *Über Dementia Infantilis: Verblödungsprozess im Kindesalter* (*On Dementia Infantilis: Mental Regression in Childhood*) in 1908, Heller described six cases he had seen in Vienna, referred from as far away as Turkey (Heller 1908). The children had all been developing normally until their third or fourth year of life, and then had dramatic losses, ultimately ending up with little or no language, and strange stereotypes of behavior. One of Heller's case descriptions is excerpted below to illustrate the period of regression:

At the end of his third year of life he developed **states of anxiety**. He didn't want to stay in a dark room. He was **afraid** when he was left alone. He often cried without cause. **Later** his intelligence decreased rapidly. He wasn't interested in games he had previously enjoyed and no longer understood them. He made strange movements and held strange postures. He played with his saliva. His speech became worse and worse.

Although the term *autism* was used to describe the inward turning aspect of schizophrenia by Bleuler, a contemporary of Heller's, around the same time that Heller was writing about these cases, it was not until many years later that Kanner and Asperger would use the term to describe the combination of social disabilities and repetitive behaviors. However, Heller's vivid descriptions of *dementia infantilis* are without question also descriptions of autism. Heller led an extremely productive life. He founded organizations (Society for Special Education, Society for Pediatric Research, Austrian Society for Special Education), contributed significantly to other organizations (International Society for Special Education), and served as an editor (*Journal of*

Child Research). Heller gave his last public speech during March of 1938. Later that month, as a Jew, he was removed from his position as head of the institute by the Nazis. His temporary replacement was a butcher. In May, Heller attempted suicide. He died on December 12, 1938, as a result. The following year, his wife and daughter were taken to Riga and killed by the Nazis. His institute was disbanded in 1941.

Hendrick Hudson Central School District v. Rowley (Provision of What Is an Appropriate Program)

Heather McKay
 Quinnipiac University School of Law, Hamden, CT, USA

Definition

Bd. of Educ. of Hendrick Hudson Cent. Sch. Dist. v. Rowley

In General

In this case, the United States Supreme Court declared that the “free appropriate public education” (FAPE) requirement in the Education for All Handicapped Children Act (EAHCA) – the Individuals with Disabilities Education Act’s (IDEA) predecessor statute – required school districts merely to provide all disabled students with educational benefits rather than to maximize each disabled student’s potential. The plaintiffs, parents of a hearing-impaired student, brought suit against the defendant school district alleging that its refusal to provide their daughter with a sign language interpreter constituted a denial of FAPE. Noting the student’s successful completion of her grade level, the Court sided with the school district by finding the FAPE requirement satisfied regardless of whether she may have performed better with access to a sign language interpreter.

In reaching this conclusion, the Court found that the Act neither expressly defined FAPE, nor imposed upon the states any substantive standard prescribing the level of education to be accorded to disabled children. The Court thus prescribed a flexible two-part inquiry for examining educational programs, whereby courts should ask: (1) whether the state complied with the procedures set forth in the IDEA and (2) whether the student's individualized educational program (IEP) was reasonably calculated to enable the child to receive educational benefits. Pursuant to this decision, a disabled student's education must merely provide the student with some meaningful benefit rather than providing the best education possible. Thus, school districts must provide only a "basic floor of opportunity" to children with disabilities, even when it is arguable that students could perform better if granted additional services.

Implications for ASD Students

Autism spectrum disorders were added to the IDEA's list of disabilities in 1991. Since then, however, much debate surrounds the issue of defining FAPE for ASD students. The low threshold announced in *Rowley* made it difficult for parents to prove that their ASD student's IEP is inadequate. The preferred early intervention programs for ASD students, such as applied behavioral analysis (ABA), are very costly and require trained personnel. District programs are often-times school-based and do not provide the student with the one-on-one attention that some experts believe is necessary for ASD treatment. Some critics argue that the "equal floor of opportunity" requirement is too vague, particularly in light of the broad spectrum of autism disorders and the wide variety of treatment options for ASD.

Litigation Strategies

It is important to note that there is much room for disagreement with respect to defining appropriate educational programs for ASD students. These disagreements pose problems for parents and professionals attempting to prove that an ASD student's IEP is inadequate under the IDEA. In addition, parents must be aware before challenging their child's IEP that IDEA litigation is expensive. Although victorious parents may sometimes

collect attorneys' fees, they are unlikely to recover such fees if they reach a settlement agreement before trial. Since 2007, though, parents have a recognized right to bring suit under the IDEA directly, without legal representation, which helps reduce the costs associated with such litigation.

Heritage Language Use for Intervention in Autism

Nataly Lim

University of Texas at Austin, Austin, TX, USA

Definition

Heritage languages are those languages that are specific to an ethnic or racial group. For instance,

the heritage language of a Chinese person might be Mandarin. An individual's heritage language may be different from the majority language (i.e., the language that is spoken by most people in a region), like in the case of a Chinese person living in the United States. For individuals with autism spectrum disorder (ASD) whose families might speak a heritage language that is different from the majority language, heritage language usage during intervention might look like (a) delivering the entire intervention in the heritage language, (b) providing verbalizations in the heritage language, or (c) teaching using heritage and majority languages.

Historical Background

Because a core characteristic of ASD is the impairment of language abilities, some parents and practitioners believed that exposure to more than one language could exacerbate the already impaired language development of children with ASD (Hampton et al. 2017; Kay-Raining Bird et al. 2012; Kremer-Sadlik 2005; Ohashi et al. 2012). As Lim et al. (2018) pointed out, the arguments against dual-language exposure mirror those that surrounded the use of augmentative and alternative communication (AAC), which is now widely used to help children with ASD communicate. Studies that have compared the language abilities of bilingual and monolingual children with ASD have found no detrimental effects of bilingual exposure (Dai et al. 2018; Gonzalez-Barrero and Nadig 2017; Lund et al. 2017; Zhou et al. 2017). In particular, Dai et al. (2018) compared the expressive and receptive language abilities of bilingually exposed to monolingually exposed children with ASD before they received any intervention. Results demonstrated that there were no detrimental effects of bilingual exposure, even when cognitive functioning and socioeconomic status were controlled for. Additionally, some studies even suggest that bilingual children with ASD might have an advantage over monolingual children with ASD in terms of vocabulary size (Gonzalez-Barrero and Nadig 2017) and early social communication skills like gesturing (Valicenti-McDermott et al. 2013; Zhou

et al. 2017). Overall, it would seem that learning more than one language does not negatively impact the language development of children with ASD.

Current Knowledge

Because research regarding the effects of dual-language exposure in children with ASD is relatively new, few studies have investigated the effects heritage language use in interventions for individuals with ASD. Seung et al. (2006) reported on a case study whereby a Korean-American preschooler with ASD received speech-language intervention entirely in Korean, then bilingually in Korean and English, and finally entirely in English. Results indicated that conducting speech-language intervention in Korean, the participant's heritage language, helped to facilitate the participant's acquisition of English, the majority language. Specifically, authors noted that the participant acquired new English words as his Korean vocabulary increased.

In terms of providing verbalizations in heritage languages, preference assessments suggest that children with ASD may prefer listening to verbalizations such as praise in their primary home language, which may be the heritage or majority language depending on the household (Aguilar et al. 2016, 2017). Bilingually exposed children with ASD's language preferences may also depend on task difficulty levels such that they prefer their primary home language as tasks become more challenging (Aguilar et al. 2016). Additionally, the language that verbalizations are delivered in may also affect children with ASD's engagement in play behaviors (Lim and Charlop 2018). Specifically, children with ASD may demonstrate more play behaviors when play partners deliver verbalizations like instructions, comments, and praise in their heritage languages.

A recent meta-analysis of studies comparing the effects of teaching children with neurodevelopmental disorders in the heritage language versus the majority language identified five studies that included participants with ASD (Lim et al. 2019). One study did not disaggregate the data of

participants with ASD from those with intellectual disability (Durán and Heiry 1986). Thus, the specific effects of providing verbal prompts in English versus Spanish on the vocational skills of adults with ASD are unclear. Of the remaining four studies, one study found that conducting discrete trial training in the participant's heritage language, Spanish, led to increased accuracy and decreased instances of challenging behaviors as compared to the majority language (Lang et al. 2011). The other three studies found no effects of language of instruction in the context of functional communication training (Dalmau et al. 2011), tact training (León 2016), and pivotal response training (Vaughn 2014). Functional communication training in Spanish and English were equally effective at decreasing challenging behaviors and increasing task completion and requests for reinforcement (Dalmau et al. 2011). Conducting tact training in English and bilingually (i.e., English and Spanish) had similar effects on correct responding (León 2016). Pivotal response training in Spanish and English had comparable effects on participants' conversation skills (Vaughn 2014).

In sum, the current literature indicates that (a) delivering speech-language intervention in the heritage language of a child with ASD might facilitate the acquisition of the majority language, (b) children with ASD from bilingual households might demonstrate preferences for their primary home language and engage in more play behaviors when verbalizations are provided in their heritage languages, and (c) heritage and majority language-based treatments may be equally effective.

Future Directions

In general, more studies investigating the effects of using heritage languages during interventions for children with ASD are needed. With preference assessments indicating that bilingual children with ASD might prefer their primary home languages, researchers may want to pay special attention to reporting the amount of exposure that participants have with heritage and majority languages within their homes. A challenge for

those conducting research in this area may be finding interventionists who are fluent in participants' heritage languages. Because heritage languages are most often spoken within the context of family, researchers may want to look at training parents or siblings of children with ASD to deliver interventions in their heritage languages. Nonetheless, if the family member is not fluent in the majority language, then the same challenge of finding a trainer who speaks the heritage language will be present. Thus, another area for future research may be investigating how training can be conducted in the presence of language barriers.

Higher Education Opportunity Act of 2008 (HEOA)

Ernst O. VanBergeijk

Vocational Independence Program, New York
Institute of Technology, Central Islip,
NY, USA

Threshold Program, Lesley University,
Cambridge, MA, USA

Definition

In 2008, Congress reauthorized the Higher Education Act as the Higher Education Opportunity Act (HEOA). This reauthorization brought about major changes to the eligibility requirements under Title IV which is the title that governs the Federal Student Aid (FSA). Now students with intellectual disabilities (ID) and developmental disabilities (DD) including some students on the autism spectrum may have an opportunity to attend postsecondary education as a result of these amendments and receive some limited forms of Federal Student Aid. This piece of legislation creates an avenue through which more students with autism spectrum disorders and other developmental disabilities can attend college.

The Higher Education Opportunity Act (HEOA) allows Institutions of Higher Education

(IHE) that already are approved to distribute Federal Student Aid under Title IV to apply to the US Department of Education (DOE) for approval of a comprehensive transition and post-secondary program (CTP). Colleges and universities would need to design a curriculum and advising structure specifically geared toward meeting the needs of students with intellectual disabilities. At least 51% of the students with ID's time would need to be spent with non-disabled peers. If the US DOE approved a college's CTP, then the student with an intellectual disability would be limited to only some forms of Federal Student Aid, namely, Federal Pell Grants, Federal Supplemental Educational Opportunity Grants (FSEOG), and Federal Work-Study monies. Although the student with ID enrolled in a US DOE-approved CTP does not have to pay back these grants, it does limit their ability to pay the high costs of post-secondary education. The bulk of Federal Student Aid is in the form of guaranteed student loans that are both subsidized and unsubsidized by the government.

An eligible student with an intellectual disability (ID) is defined in Section 760 of the HEOA (with slight modifications) and includes a student (A) with mental retardation or significant cognitive impairment and (B) who is/was eligible for FAPE under IDEA including students who were private and/or homeschooled. The student must be enrolled in an approved CTP and must meet all of the general student eligibility requirements under Section 668.32 **except:**

- Does *not* have to be enrolled for the purpose of obtaining a degree or certificate
- Is *not* required to have a high school diploma or have passed an ability-to-benefit test
- Must maintain satisfactory academic progress under school's policy for students in the CTP (Bergeron et al. 2010).

The student must also have a documentation demonstrating that he or she has an intellectual disability or significant cognitive impairment which can also include individuals with autism spectrum disorders (VanBergeijk and Cavanagh 2012).

An eligible CTP must be offered by a college that already has an established financial aid program for its general student body. It also must be specifically designed to support students with intellectual disabilities (ID) and include an advising and curriculum structure. The CTP must require students with ID to participate in courses and activities with students without disabilities. These activities can include vocational internships in addition to academic coursework (VanBergeijk and Cavanagh 2012).

Students with ID and/or significant cognitive impairments including those students on the autism spectrum can complete the Free Application for Federal Student Aid (FAFSA) and receive aid provided they are intending to enroll in a US DOE-approved CTP. The FAFSA form helps the college determine how much aid a student enrolled in a CTP is entitled to by calculating the Expected Family Contribution (EFC) (Finkel et al. 2010).

Historical Background

The Higher Education Opportunity Act can trace its roots to the Higher Education Act of 1965 (P.L. 89–329). This act authorized most federal student financial aid programs, including the Federal Supplemental Educational Opportunity Grant program and the guaranteed student loan program (FinAid 2016) (known as Title IV). At the time President Lyndon B. Johnson signed the act into law, the proportion of grants to loans is the mirror opposite of what they are today. In the 1960s, about 2/3 of the Federal Student Aid came in the form of grants. Now that proportion is inverted with 2/3 of today's Federal Student Aid being given to students in the form of loans.

Prior to the passage of HEOA, only students who were enrolled full time in a degree-bearing program were eligible for Federal Student Aid. Full-time students were able to complete the Free Application for Federal Student Aid (FAFSA). The student was eligible for both subsidized and unsubsidized guaranteed student loans as well as grants including Federal Pell Grants, Federal Supplemental Educational Opportunity Grants (FSEOG), and Federal Work-Study program funds. The Congress was amending the

act in the midst of the worst economic recession since the Great Depression. A driving force behind the recession was the provision of risky mortgage and business loans. Consequently, the Congress decided not to allow students with ID to be eligible. The thought was that the students with IDs' debit to income ratio would be too high for them to be able to pay off the debt. Therefore, this population of students was perceived as being yet another risky loan prospect. Interestingly, Wehman (2001) found that students with disabilities who did complete a college degree were employed at a rate that was not statistically different from their nondisabled peers. Many individuals on the autism spectrum have the capacity to complete college level work. It is their impairment in executive functioning, independent living, and social skills that make it difficult for them to complete a degree – not their intellectual ability. This blanket policy of excluding this population needs further examination.

Current Knowledge

Although the HEOA was passed in 2008, it was not until 2011 that the US DOE began taking applications from Institutions of Higher Education (IHE) to have their comprehensive transition and postsecondary programs (CTP) approved to distribute Federal Student Aid. Despite the fact that there are over 7600 IHE that are authorized to disperse Federal Student Aid under Title IV, only about colleges have a US DOE-approved CTP. This represents that less than of colleges and universities are serving this population through the CTP structure.

The reasons for the slow adoption of the CTP model by our nation's Institutions of Higher Education are unclear. The law was enacted with little fanfare considering this provides students with ID an entrée into postsecondary education. The actual implementation of the law took a number of years and appeared to be not well coordinated. There were high administrative costs incurred by the universities to undertake the creation of a CTP with little economic incentive to commit the organization's resources. Perhaps, if the legislation had also included the provision of student loans to students with ID enrolled in a CTP, then more

colleges of universities may have created these programs for students with ID.

What we know from current research is that postsecondary transition programs do make a difference in the employment outcomes of students with intellectual disabilities. Moore and Schelling (2015) found that nine out of ten students who graduated from a postsecondary program were employed within 2 years of their study. This is in contrast to the finding from the National Longitudinal Transition Study-2 that only about half of the students with intellectual disabilities were employed (as cited in Moore and Schelling 2015). Wehman et al. (2013) used postsecondary vocational training as an intervention in a randomized clinical trial. His team's finding was that 87.5% of the students on the autism spectrum who participated in the postsecondary vocational training were employed at the end of the study, whereas the control group, which consisted of students working with their high school and their state office of Vocational Rehabilitation Services, had an employment rate of 6.5%.

Future Directions

In order for the CTP model to gain traction, three things need to occur. First, research into the efficacy of this model in general needs to be conducted. We need to examine not only if these models improve the employment outcomes of individuals with ID/DD and autism but also whether or not these individuals are making a living wage, are able to live independently, and are engaged in their communities with meaningful connections such as friendships and affiliations with organizations including civic, recreational, and religious organizations. More sophisticated research should examine the structural differences in the CTP that promote positive outcomes with this population. Given the broad nature of the requirements of a CTP outlined by HEOA, there will be a great deal of variance in the programs' offerings and structure. Some CTP will have a residential component. Others will simply stand as a day program where the students commute daily to campus. The academic offerings will also vary widely with some colleges allowing

students with ID to simply audit credit-bearing courses. Others will encourage students to take coursework for credit. Another possible structure is that the CTP offer vocational training and pre-employment skills readiness courses.

With the passage of the Workforce Innovation and Opportunity Act (WIOA), colleges and universities need to learn that a substantial amount of government funding is available for programs and services directed to transitional age youth with disabilities. Institutions of Higher Education are eligible to be providers of preemployment services. The law not only specifically designated IHEs as potential partners but also mentions CTP as being potentially eligible for funding as well. Only when universities realize this potential funding stream is available will the CTP model gain traction.

The final change that needs to occur before the CTP model will become more widespread is amending the HEOA to allow students with ID/DD to obtain student loans. The rationale for not allowing this population of students to receive the federal student loans is that their ability to repay those loans is perceived as being low. The unintended consequence of this feature of the HEOA is that a number of families are turning to private lenders for continuing education loans in order to finance their sons' and daughters' attendance at a CTP. These loans are much more expensive for families to maintain and are more likely to result in a default in the loan than the government-provided subsidized and unsubsidized loans at lower rates of interest.

Definition

High-functioning autism is a term used to refer to a subset of individuals on the autism spectrum who have cognitive and/or linguistic abilities

that are in the average to above-average range for their age. It is common for the acronym “HFA” to be used to describe individuals in this range of functioning.

Historical Background

In the first characterizations of the disorder, both Kanner and Asperger noted average to above-average intellectual capabilities in the individuals they observed, despite their significant social deficits. Kanner argued explicitly in several papers that social deficits were separable from intellectual disability and that most of the children he encountered were of average to above average intelligence. Interestingly, Asperger used the “special gifts” of the children he observed to advocate for their protection from the Nazi eugenics movement (Feinstein 2010).

Historically, testing IQ in children on the autism spectrum was difficult (Alpern 1967; Alpern and Kimberlin 1970). Although many of the children had discernible strengths (and sometimes savant skills) in areas of cognitive function, language and social deficits often interfered with standardized administration of tests. Moreover, even individuals on the autism spectrum who did not exhibit specific savant skills often showed pronounced relative strengths and weaknesses from subtest to subtest that made generating an overall IQ score difficult. In one of the earliest instances of the use of “high-functioning” as a term in reference to individuals with ASD in a research study, DeMeyer and colleagues suggested that children who currently were defined as “high-functioning psychotic children” should be reclassified as children with “high-functioning infantile autism” (DeMyer et al. 1971). They used the term “high-autistic children” to refer to a group of children with IQs within two standard deviations of the mean or higher.

The term “high-functioning autism” was used infrequently until the late 1980s, when Asperger syndrome grew in popularity as a distinct diagnosis. At that time, “High-functioning autism” was used to describe the subgroup of individuals with autism who had average or above average intelligence or language abilities to compare them to

individuals with Asperger syndrome (e.g., DeLong and Dwyer 1988). The use of the acronym “HFA” also began at around this time (e.g., Szatmari et al. 1989).

Recently, the use of the term “high-functioning” has become a common qualifier in research studies and for clinical diagnoses. In research, its use is common in part because a significant portion of published research is conducted on this subset of individuals with autism spectrum disorder (ASD). Individuals with average to above average IQs/language abilities are overrepresented in research because of the behavioral challenges in conducting research on individuals with ASD and intellectual disability.

The term HFA is sometimes used in clinical evaluations, even though it is not currently an established diagnostic category. In DSM-5 criteria for ASD, there is an item that categorizes “Severity Level,” but these categories do not include the term HFA. The categories are “Level 1 – Requiring Support,” “Level 2 – Requiring Substantial Support,” and “Level 3 – Requiring Very Substantial Support.” Each diagnostic criterion receives its own Severity Level score. It is likely that most individuals with an HFA label would fall under “Level 1,” although it is possible that somebody who is considered high-functioning could still require substantial support in one or more areas. Deficits at Level 1 are described as causing noticeable impairments without supports in place, whereas impairments in the higher levels (2 and 3) are noticeable even with appropriate supports in place.

Current Knowledge

“High-functioning” is a qualifier that is commonly used to describe a subgroup of individuals on the autism spectrum, but currently there is no recognized definition or criteria for inclusion in this group, either clinically or in research. The term high-functioning has been used: (a) to differentiate this subgroup of individuals on the autism spectrum from a group with intellectual disability (i.e., “low-functioning”), (b) to differentiate it from a group with an Asperger syndrome

diagnosis, and (c) to compare it a typically developing comparison group or to specify an individual's level of cognitive and/or language ability in the context of a research study.

In research, inclusion criteria can vary from study to study. Minimally, group membership is defined as having either an intelligence test or language test standard score above 70 (or within two standard deviations of the mean or above, if the test uses a different statistic). Some studies use more stringent criteria, such as requiring both language and cognitive standard scores to be above 70. Other studies will require one or both language/cognitive scores to be above 80, which would exclude individuals who have scores in the "borderline" range of intellectual functioning (standard 70–80). Still other studies will use criteria that exclude individuals with standard scores below 85 (i.e., one standard deviation below the mean) on standardized language and/or cognitive tests. These stringent criteria include only individuals that are at or above the typical range of functioning, as defined by standardized testing.

Even though the term "functioning" is included in the label, adaptive functioning level is generally not considered when using the terminology. "Functioning" is generally used to refer to cognitive and/or linguistic functioning. This is not consistent with the conceptualization of intellectual disability; the intellectual disability definition includes both cognitive and adaptive functioning in the criteria.

High-Functioning Autism Versus Asperger Syndrome

The increased frequency of the use of the term HFA has been due in part to the addition of Asperger syndrome as a diagnostic category. In the Diagnostic and Statistical Manual of Mental Disorders, 4th Edition (DSM-IV), individuals with Asperger's Disorder meet the criteria for social impairment and restricted/repetitive behavior necessary for a diagnosis of Autistic Disorder but are not required to meet requirements for impairments in communication and do not show

delays in early language milestones. In addition, individuals with an Asperger syndrome diagnosis must have shown no delays in cognitive development. It was known, however, that a subgroup of individuals with the autistic disorder diagnosis also showed no delays in cognitive development, which necessitated comparisons between the two groups to understand categorical differences.

There has been a considerable amount of research comparing individuals with the diagnosis of Asperger syndrome to individuals with HFA in order to determine if there are categorical differences between the autism and Asperger syndrome diagnoses. Some of the factors that have been proposed as differences between individuals with Asperger syndrome and HFA include (but are not limited to) presence/absence of delays in reaching language developmental milestones, motor skills/clumsiness, types of restricted/repetitive behavior displayed, and speaking style (including prosody), among other characteristics. Research has shown that DSM-IV criteria do not yield meaningful and categorical differences between Asperger syndrome and HFA. As a result, Asperger syndrome was removed from the newest version of the DSM, although this change generated considerable controversy. One argument against the change is that the problem in differentiating the groups might be an artifact of imprecise diagnoses, rather than the absence of categorical differences.

It is likely, however, that, even with the elimination of Asperger syndrome as a diagnosis in DSM-5, the use of the "high-functioning" qualifier (e.g., "high-functioning ASD") will continue. In the past several years, research studies have begun to refer to children with Asperger syndrome and HFA together as a group of individuals with "high-functioning ASD."

Future Directions

For clarity, it will be important to set clear criteria for what constitutes high-functioning autism, for both research and clinical purposes. To date, it has been difficult to make meaningful comparisons across research studies because of the wide

variety of ways group membership has been defined in research studies. For research studies, criteria should include *both* language level and cognitive level when defining a group as “high-functioning.” Moreover, groups defined as “high-functioning” should strongly consider excluding individuals with cognitive or language abilities below one standard deviation from the mean and above the cutoffs for intellectual disability or language impairment (i.e., individuals with IQ and Language standard scores between 70 and 85). These more stringent criteria are more consistent with the idea that the group is “high-functioning.” Moreover, these criteria create a more homogeneous group that is more easily matched with a typically developing comparison group, both on mean and standard deviation of scores.

Second, it will be important to consider adaptive functioning, in addition to cognitive and language level, when defining using the term “high-functioning.” The use of adaptive functioning in the high-functioning criteria will provide a definition that is more consistent with the definition of Intellectual Disability, which includes both intellectual and adaptive functioning. Moreover, the inclusion of adaptive functioning in the definition is a more valid representation of level of functioning, because individuals with ASD can have significant discrepancies between cognitive and adaptive functioning, and language/IQ scores may not be representative of level of functioning for some individuals.

In clinical settings, clear criteria would be important, but only if it is determined that there are clinically relevant benefits of using a “high-functioning” qualifier. It is important to investigate whether there are specific intervention recommendations that can be tailored to individuals with this qualifier.

Finally, it should also be investigated whether the addition of the “high-functioning” qualifier lessens the stigma of the diagnosis, and if the qualifier changes the way that parents, peers, and/or professionals interact with the child or the family. Research on other disabilities has shown that adding levels of ability in a label increases the stigma associated with individuals on the “lower” end of ability. It is possible that the high-

functioning qualifier reinforces stigma associated with portions of the population who are not considered high-functioning.

High-Probability Requests

Mary Jane Weiss and Samantha Russo
Institute for Behavioral Studies, Endicott College,
Beverly, MA, USA

Definition

High-probability request sequence is an intervention used to increase compliance. It is a

nonaversive intervention commonly used to treat noncompliance by reducing escape-motivated behavior. It is also associated with and has been historically referred to as interspersed requests, pretask requests, and behavioral momentum. It is considered an antecedent intervention.

The basic procedure involves the teacher presenting three to five “high-probability requests,” which are easy and quick responses already mastered by the child and highly likely that the child will emit. The teacher presents these requests quickly, one after the other, providing brief verbal praise after each one. Immediately after receiving praise for the last of these high-probability requests, the teacher immediately presents the request to which the child has historically not complied. Reinforcement can also be added to the high-probability sequence to effectively increase compliance with low-p instructions (Wilder et al. 2015).

The use of the high-p sequence often prevents the noncompliance. Responding is facilitated (and momentum is built) through the high-p requests. Theoretically, the effect of the high-p sequence stems from the abative effects of an abolishing operation (AO). It reduces the value of reinforcement for noncompliance to the low-probability requests. The value of escape from demands is lowered. In application, behavior analysts must ensure that the high-p response request intervention is not done after the occurrence of a problem behavior. Such use could inadvertently strengthen escape-motivated noncompliance. In addition, attention must be paid to the quality of reinforcement delivered for compliance, especially if behaviors are severe (e.g., Mace and Belfiore 1990). Finally, the number of high-probability requests can be gradually reduced as compliance with low-probability requests improves.

Hippocampus

Ilanit Gordon
Child Study Center, Yale University, New Haven,
CT, USA

Definition

The hippocampus is a bilateral incurved brain structure, a coiled elongated ridge located beneath the neocortex in the basal medial surface of the temporal lobes. Comprising a major component of the limbic system, the hippocampus is phylogenetically considered an ancient brain structure. It was first coined hippocampus by the sixteenth-century Italian anatomist Julius Caesar Aranzi who likened its shape to that of a seahorse (in Greek hippo = horse, kampe = curve). The hippocampus is mostly implicated in processes of memory formation and consolidation as it is critical for the formation of new factual and autobiographical memories. Hippocampal damage can result in anterograde amnesia: the loss of ability to form new memories. The hippocampus is also known for its involvement in the coding of spatial information, navigation, and orientation.

Hippotherapy

K. Mark Derby, Anjali Barretto and
Tim MacLaughlin
Department of Special Education, Gonzaga
University, Spokane, WA, USA

Definition

Hippotherapy is a treatment that uses the multi-dimensional movement of the horse. The term hippotherapy comes from the Greek word “hippos” which means horse. Specially trained physical, occupational, and speech therapists use this treatment for clients who have movement dysfunction and social deficits. The central tenant of the intervention is to use the movement the client experiences while on horseback to improve physical capabilities while developing a therapeutic relationship (All et al. 1999; Bass et al. 2009).

Historical Background

Pet ownership has been shown to be beneficial for individuals with a wide range of diagnoses (Voelker 1995). Pet or animal therapy is based on the assumption that interactions with animals can cause both physiological changes and psychological benefits (All et al. 1999). For example, Lehrman and Ross (2001) reported an increase in verbal sounds made by a 9-year-old girl with visual impairments when pet therapy was employed. In addition, children diagnosed with autism have been shown to make improvements in communication when animal-assisted therapy has been employed (Blue 1986). Social skills have

been taught to children with autism via the use of animal therapy (Law and Scott 1995; Turner 2005). Horseback riding has been shown to benefit children with communication disorders (Health and McKinney 1989). There have also been a few anecdotal reports that horseback riding and hippotherapy can have recreational and social benefits. Bass et al. (2009) evaluated the effects of horseback riding on the social functioning of children with autism. Utilizing a wait-list control design, those authors were able to demonstrate the efficacy of the interventions for increasing children's sensory seeking, sensory sensitivity, and social motivation. In addition, an inverse relationship was observed for problem behaviors such as inattentiveness and distractibility. Its use for children with autism spectrum disorders (ASD) is in its infancy, but the preliminary data are promising (Bass et al. 2009).

Rationale or Underlying Theory

At this time, the underlying theory for why hippotherapy has been beneficial appears to rely on both physiological and environmental factors (Macaulay and Gutierrez 2005). Hippotherapy is believed to help an individual develop an awareness of body movement, weight distribution, improved hand-eye coordination, improved speech, a wider tactile experience, and a wider experience of sounds (Macaulay and Gutierrez 2005). In a descriptive evaluation of therapist perceptions in Germany and Britain, Debuse et al. (2005) found that most practitioners of hippotherapy believed that hippotherapy improved the rejuvenation of muscle tone, improved postural control, and resulted in psychological benefits. However, these findings relied on the self-report of practitioners. Environmentally, the positive outcomes could be hypothesized to occur based on applied behavior analysis literature. For example, Carr and Durand (1985) demonstrated that through differential reinforcement, severe behaviors are reduced and a covariant increase in communicative behavior occurrences. Similarly, Derby et al. (1997) reported that if the child is provided an alternate

form of communication to obtain identified reinforcers (e.g., increased horse movement), appropriate social behavior increases. Thus, increased social behavior could be the function of a reinforcer/behavior contingency. Within the context of hippotherapy, the contingency would be between horse movement and social behavior.

Goals and Objectives

Physiologically, through the movement of the horse, the goal of hippotherapy is to help an individual develop an awareness of body movement, weight distribution, improved hand-eye coordination, improved speech, a wider tactile experience, and a wider experience of sounds (Macaulay and Gutierrez 2005). It is also used as a treatment tool by speech pathologists to increase the social motivation (Taylor et al. 2009), sensory seeking and sensitivity (Bass et al. 2009), and social behavior (Nelson et al. 2006).

Treatment Participants

Hippotherapy has been used as a therapy technique and is primarily used for persons with physical impairments (Benda et al. 2003) and speech impairments (Bass et al. 2009; Taylor et al. 2009).

Treatment Procedures

Occupational therapists, speech-language pathologists, and physical therapists typically perform the practice of hippotherapy. Even though every specialty derives its effectiveness from the unique movement of the horses, each enters the therapeutic environment with their own unique goals. Physical therapists target functional skills such as sitting, standing, and walking. Conversely, speech-language therapists use the therapy to remediate student communication. Each therapy modality relies on the movement of the horse to improve client function. Typical therapy sessions may last between 45 and 60 min. The therapy session is often broken down into distinct

segments, which may include putting on protective equipment such as a helmet, mounting the equine, engaging in activities while with horse, and dismounting the horse. For a safe and effective experience, a minimum of four trained professionals are required to complete a therapeutic session. A trained horse leader is always present who is responsible for prompting all horse movements. Two side-walkers are placed on either side of the equine to ensure client stability and safety. A lead therapist is assigned who is responsible for all therapeutic activities. Once mounting the equine activities is achieved, the procedures used focus on the individual needs of the client. The client may be seated on the equine a number of ways including sitting forward or sideways. Therapy is focused on the use of activities that are meaningful to the client and also meet treatment goals. For example, Benda et al. (2003) evaluate the effects of 8 min of a steady walking movement (4 min clockwise followed by 4 min counterclockwise) versus a stationary board control condition with children with spastic cerebral palsy. These authors found that following as little as 8 min of therapy, significant improvement in symmetry of muscle movements occurred. As an adjunctive speech intervention, Nelson et al. (2006) utilized a functional communication approach to increase the vocalizations of three children with autism spectrum disorder. In the Nelson et al. investigation, the children were required to sign or say "please" to prompt the horse handlers to start, stop, turn, and change the stride of the horse. The researchers found that the children's use of the functional communication and other social vocal responses increased. Nelson et al. hypothesized that the horse functioned as a reinforcer for appropriate communications. Similarly, Bass et al. (2009) exposed children with autism to 12, 1-h treatment sessions of hippotherapy across specific activities. Specifically, the therapist prompted the children to engage in a number of horse-related activities which included mounting/dismounting, riding skills, movement games (i.e., Simon says, catch and throw, etc.), and horse grooming. These investigators found that the children who participated in therapy exhibited increased sensory seeking, sensory sensitivity,

and social motivation. Regardless of the specific professionals conducting the therapy (i.e., occupational therapy, speech therapy, physical therapy), sessions are individualized in order to obtain functional goals for the client.

Efficacy Information

Overall, the literature found supports the efficacy of hippotherapy is in its infancy for increased social functioning (Bass et al. 2009). Conversely, the use of the horse as a therapeutic tool to increase posture, balance, and overall functioning of persons with motor dysfunction is better documented. For example, Benda et al. (2003) reported that hippotherapy could increase the symmetry of muscle activity when compared to sitting astride on a barrel using surface electromyography as an outcome measure. Positive effects have also been reported and have produced improved posture and balance for persons with cerebral palsy (Zadnikar and Kastrin 2011).

Outcome Measurement

Outcome measures vary depending on the focus of therapy. If therapy is focused on improving physical attributes, outcome measures range from the therapist using researcher-made objective scoring scales, weight bearing, and standardized measures such as the Gross Motor Function Measure (Russel et al. 2000) or the Pediatric Evaluation of Disability Inventory Scale (Feldman et al. 1990). In addition, surface electromyography has been used to measure muscle activity (Benda et al. 2003). If therapy is focused on social skill and motivation, measures typically involve the use of questionnaires and direct observational data collection systems. Bass, Duchowny, and Llabre documented sensory outcomes using the Sensory Profile (Dunn 1999) and increase social functioning and motivation using the Social Responsiveness Scale (Constantino 2002). Conversely, Nelson et al. (2006) measured increased social behaviors via in vivo measurement of child behaviors and vocalizations.

Qualifications of Treatment Providers

Licensed occupational therapists, physical therapists, and speech-language pathologists typically practice hippotherapy. A majority of the professionals that practice hippotherapy do not have a formal certificate beyond the qualifications for one of these professions. However, the American Hippotherapy Association has established a certificate process. Persons with these credentials need to have practiced their profession for 3 years, have 100 h of hippotherapy practice, and passed a multiple-choice examination.

Histidinemia

Jeffrey P. Brosco

Department of Pediatrics, Miller School of Medicine, University of Miami, Mailman Center for Child Development, Miami, FL, USA

Definition

Histidinemia is an essential amino acid during infancy. In the 1960s, disorders of histidine metabolism were thought to be associated with

speech delay and intellectual impairment. There were also multiple case reports noting the co-occurrence of histidinemia and various disorders, including autism. Using newborn screening and dietary management of phenylketonuria as a model, New York and Massachusetts implemented newborn screening programs for histidinemia. By the late 1970s, histidinemia was understood as a benign metabolic variant, and enthusiasm for state-sponsored newborn screening for histidinemia has become a cautionary tale.

History of Autism as a Diagnostic Concept

John Donvan¹ and Caren Zucker²

¹Washington, DC, USA

²New Jersey, USA

Historical Background

Among the many questions that surround autism, one likely never to get a solid, uncontroverted answer is the following:

How far back in human history does autism go?

It is obvious that at some stage in our species' development, some person was first to display the behaviors we today call "autistic." To date, however, we have no way to identify when or where that happened on the timeline of human evolution. There are no direct fossils for behavior. Despite that, it seems reasonable and intuitive to assume that the autism's defining behaviors, relative to our own time, are nothing new – and that a thousand years ago, there were people acting in ways which, if they were observed today, would prompt a modern-day diagnosis of autistic spectrum disorder (ASD).

That such individuals were *not* diagnosed during their own lifetimes, over most of those ten centuries, owes to a simple fact that autism, *as a diagnostic concept*, achieved recognition only remarkably recently, coming into existence, in the minds of medical observers, only around the time that World War II was getting started.

Before that, people exhibiting such behaviors, if they were pronounced enough, risked getting pinned with some other label inevitably suggesting either mental illness or intellectual disability. The sorts of hurtful-sounding terms used in the past – lunatic, psychotic, demented, idiot, imbecile, retarded, among many others – were actual clinical categories in their day, before lay society twisted them into slurs. They also had consequences. Starting in the nineteenth century, especially in the more "advanced" societies of Europe and North America, people so labelled were increasingly pushed out of mainstream society and shunted off to supposed "asylums" or "training schools." Initially launched with therapeutic and educational aspirations, these institutions all too often decayed into soul-destroying human warehouses, overcrowded, underfunded, and inhumane. Lost within their populations, where their cluster of "odd" behaviors were not recognized as distinctively meaningful in any way, were many people with today's ASD. They were lost, in part, because no one had ever heard of autism.

Current Knowledge

In 1943, a child psychiatrist named Leo Kanner published a groundbreaking description of 11 children, in which he made the case in vivid detail that their short histories merited a new kind of diagnosis. These eight boys and three girls were clearly not typical in their development – to the extent, Kanner wrote that "several... were introduced to us as idiots or imbeciles." Following the usual pattern, most of the children, none older than 11, had already been sent off to institutions, some given diagnoses of "feble-mindedness" or schizophrenia. To Kanner's eyes, however, there was something seriously wrong with these assessments. The example of the boy he designated "case 1" demonstrates why.

"Donald T" was 5 years old in 1938, the first time his concerned parents brought him from Mississippi to be seen by Kanner at his clinic at Johns Hopkins University. In describing Donald, Kanner relied on his own and his staff's

observations, then and over the next few years, while also quoting liberally from a lengthy description of his behaviors written by Donald's father: "It was observed at an early time that he got happiest when left alone. . . He paid no attention to persons around him." He had never cried for his mother and never noticed his father's arrivals home from work. Yet inanimate objects fascinated him, and he "developed a mania for spinning blocks and pans and other round objects." His speech was unusual too. Donald was using words by 13 months, but he reversed the pronouns "you" and "I" and spoke with a flat intonation. When asked a question, his answer was to recite the question, verbatim, followed by silence. Otherwise, his utterances consisted mainly of the same small set of phrases, such as "I could put a little comma or semicolon," which he had once heard someone else say and then taken to speaking aloud in a ritualistic manner.

Finally, Kanner noted, Donald hated change and cherished repetition.

Most of his actions were repetitions carried out in exactly the same way in which they had been performed originally. If he spun a block, he must always start with the same face uppermost. When he threaded buttons, he arranged them in a certain sequence that had no pattern to it but happened to be the order used by the father when he first had shown them to Donald. There were also innumerable verbal rituals recurring all day long. . . [which his mother had to comply with] or else he squealed, cried, and strained every muscle in his neck in tension.

But there was something else: Donald was clearly gifted in some areas. His memory was prodigious, and he was very quick at absorbing information.

At the age of 1 year 'he could hum and sing many tunes accurately.' Before he was 2 years old, he had 'an unusual memory for faces and names, knew the names of a great number of houses' in his home town. . . He knew the pictures of the presidents and knew most of the pictures of his ancestors and kinfolks on both sides of the house. He quickly learned the whole alphabet 'backward as well as forward' and to count to 100.

To Kanner, such talents ruled out intellectual disability as an explanation. Schizophrenia made no sense either, since its symptoms typically first manifest in adolescence and include

hallucinations, which were no part of Donald's presentation.

At the same time, Kanner did discern a few overarching patterns in Donald's behaviors and in those of the other ten children he described, which he judged significant. One was their distinct relationship to, and use, of language. Another was an "obsessive need for sameness." A third was what Kanner referred to as "autistic aloneness." Critically, too, Kanner concluded that these traits were "innate," "inborn," and present "from the beginning of life." He declared these as the key aspects of the syndrome, when he published his findings, in 1943, in a paper entitled "Autistic Disturbances of Affective Contact."

Kanner's choice of that adjective – *autistic* – proved consequential. It was not his invention. By 1943, it was already in use, and familiar to psychiatrists – along with the noun form *autism* – but in a context significantly different from the one Kanner was introducing. Till that time, adjective and noun alike had served to label exclusively a transient symptom in adults with schizophrenia: their tendency at times to disengage from contact with their external surroundings and the people in them. Such patients entered "a world of their own. . . encased with their desires and their wishes," wrote the Swiss psychiatrist Eugen Bleuler in 1911. Indeed, Bleuler himself came up with the term. "This detachment from reality and absolute predominance of the inner life, he wrote, "*we call autism*." He based it on the Greek word *αὐτός*, which means "self."

Kanner did not attempt to anoint his syndrome "autism" in 1943, when he used the noun form of the word only once in the 34 pages of his journal article. Instead, he made liberal use of Bleuler's adjective "autistic" as a descriptor – a way to get across *some* aspects of what his children's behaviors resembled. But, as Kanner saw it, the comparison went only so far, as he made clear that this rough resemblance to schizophrenic autism – what he referred to as "extreme aloneness" – was but part of the total story. "The total picture," he pointed out, included additional behaviors such as "obsessiveness, stereotypy and echolalia," which fell outside the boundaries of autism as the term's coiner defined it. Certainly, Kanner's

contemporaries grasped these nuances, and for years afterwards, when requiring a name for the syndrome Kanner had described, chose to call it, not “autism” but “Kanner’s syndrome.”

Notably, a similar borrowing of Bleuler’s concept took place, at nearly the same time, in Vienna, where a pediatrician named Hans Asperger had published work in German in 1938 and 1944, describing a number of Austrian boys struggling significantly in the domain of interpersonal relationships. Their challenges, as Asperger described them, resulted from a syndrome of obliviousness to social cues, inflexibility in behavior, and a tendency to develop obsessive interests in narrowly limited subjects. Overall, Asperger’s boys differed in significant ways from Kanner’s group, exhibiting greater capability for independence, creative output, and intellectual performance (above average in some cases) than the children Kanner wrote about. In short, Asperger highlighted children who were likely to struggle socially throughout life but were less likely to be institutionalized. And where Kanner considered his syndrome to be “rare enough,” Asperger saw his as “not at all” rare.

Like Kanner, however, Asperger used Bleuler’s autism as a reference point, and in a similar way, to suggest a rough resemblance to some aspects of schizophrenia’s social detachment. Again like Kanner, he did not call his syndrome “autism” (though, confusingly, the definitive English translation of his 1944 paper has him doing so, in more than 20 instances) but employed the adjective in describing his boys as “autistic psychopaths” and in the title of his major paper on the subject “Autistic Psychopathy in Childhood.” It should be noted that the term “psychopathy” in German best translates to English as “personality disorder,” without the negative connotations the word carries in English.

That both men made the same word choice has been put down by some to mere coincidence and by others to the normal cross-pollination of ideas that occur in science and medicine. In fact, Kanner employed a former colleague of Asperger’s, a Jew fleeing Vienna ahead of Nazi persecution whom also Jewish Kanner helped reach the United States

and with whom he could well have shared insights. As it happened, however, for the next 40 years, Asperger’s writing about boys he called “autistic” went largely overlooked outside the German-speaking world, while Kanner’s proved definitive everywhere else.

Why does autism’s etymological lineage merit focus at all? Because in it lie the origins of a major and enduring obstacle to studying, treating, and even talking about the disorder, one that remains operative to this day, namely, that from the beginning, well-intentioned voices have disagreed vigorously about what autism actually is, how to describe it, and where to draw its boundaries. This started with the terminology, a problem the astute British child psychiatrist and autism researcher Michael Rutter pointed to in 1978, when he lamented: “To begin with, there was the unfortunate choice of name.” As Rutter explained, this caused immediate confusion, owing to the unintended implication that these children had schizophrenia after all. Kanner played an unintentional part in that. In 1944, in an effort at clarity, he began referring to his syndrome as “early infantile autism.” He did this to reemphasize that the “extreme aloneness” – the “autism” which comprised but one part of the picture – was there from the start, from infancy. Notably, this was *his* first use of the noun form in this manner, and, with hindsight, it marks the moment where his descriptions of autistic-like behaviors began shaping up into a new “-ism” of their own. In the short term, however, calling his condition *autism* only muddled the waters for the many who knew the term solely by connection to schizophrenia.

A few years after Kanner’s initial paper, a remarkable sort of diagnostic melee ensued from the confusion. On the one hand, other researchers and clinicians began bringing forth new reports of children under their care similar in presentation to Kanner’s but under diagnoses they packaged according to slightly different parameters and under disparate names – for example, “symbiotic psychosis,” “prepubertal schizophrenia,” “infantile psychosis,” and “atypical child.” Again, Rutter put his finger on the problem: “It is by no means clear that all these authors are talking about

the same condition.” Then, too, it was by no means clear they weren’t.

On the other hand, and at the same time, there were many clinicians who positively embraced Kanner’s syndrome but who interpreted the diagnostic criteria far more loosely than he ever did. By the mid-1950s, Kanner was complaining about autism diagnoses being rendered merely for “one or another isolated symptom,” inflating the number of cases out of all proportion to reality. “Almost overnight,” he later said of this early period, “the country seemed to be populated by a multitude of autistic children.”

Such diagnostic disorder of course played havoc with the lives of people being given these labels, who in this period were entirely children. It also confounded attempts to conduct scientific research on autism. How, for example, were epidemiologists to determine a prevalence rate of autism when there was such profound disagreement on what constituted its necessary and sufficient symptoms?

This was exactly the issue faced by a London-based psychology graduate student named Victor Lotter, who in 1964 attempted the first-ever prevalence study of autism among the population of boys and girls aged eight to ten living in Middlesex County, England – a total of 78,000 children. When Lotter turned to the medical literature to construct a checklist of behaviors that were flags for autism, he discovered a definitional din: numerous competing portraits of the condition which, taken together, yielded little clarity but instead established – as he said with chagrin – “the lack of agreed behavioural criteria.” Pressing on, however, Lotter improvised by combining some of Kanner’s criteria with several from a list known as Creak’s nine points. With these as his starting point, Lotter in 1966 reported a prevalence rate of autism of 1 in 2500 among his cohort in Middlesex. But even as he did so, the intellectually honest student sent up a critical warning that his finding should not be considered dispositive. “‘True’ prevalence,” Lotter wrote near the end of his report, “may not be a useful concept in the case of a syndrome (or syndromes) so poorly defined.” Despite that, to this day, advocacy groups cite

Lotter’s 1 in 2500 result as representing a solid fact: what the *global* prevalence rate of autism “used to be.”

Efforts to standardize criteria for the diagnosis would preoccupy stakeholders for years to come. Continuing frustration over the issue appeared regularly in the scholarly literature, literally for decades. The following are some examples:

- In 1968, Michael Rutter was writing, not for the last time, about the “hopelessly confused state of affairs.”
- In 1978, Eric Schopler, of the University of North Carolina, was arguing that scientists working on autism were not understanding one another’s research “because criteria for diagnosis are different.”
- In 1988, Yale’s Fred Volkmar and Donald Cohen were voicing frustration over the “long and controversial history of the concepts surrounding autism.”
- In 1998, Yale’s Ami Klin, joined by Volkmar, was underscoring “the confusion and the plethora of diagnostic concepts.”

Schopler’s comment, in particular, illustrates but one ramification of this diagnostic confusion: disputes over criteria tended to confound research. Perhaps more insidious than mismatched symptom lists – for the sake of people getting diagnosed – was the clash over basic *concepts* of autism – the term used by Volkmar, Cohen, and Klin. A syndrome so prone to definitional malleability (largely because it offered no clear biomarkers but has been based on the interpretation of behaviors) also lent itself to rather disparate theories concerning its essential nature. Even as they came up short as universal explanations for autism, many of these represented coherent and insightful ideas while doing little harm. For a time, for example, one theory held that the core deficit, at least in more classic cases of autism, was a failure in the facility of language and that all other symptoms, including social challenges, flowed from that. Other ideas placed compromised cognitive functions at the center, with much attention given to the part played by

“theory of mind” and “weak central coherence.” Still others went down more biological paths, seeking to understand whether sensory issues, and even metabolic ones, were at the heart of the disorder.

And then there was the so-called psychogenic model of autism, which caused enormous harm to autistic individuals and their families. Better known as the “refrigerator mother theory” and dominant from the late 1940s at least into the mid-1970s, this concept of autism held that the disorder was a child’s defensive reaction to insufficient maternal love. Treatment, such as it existed, centered on intensive psychotherapy of the mother (and sometimes the father as well). Reflecting the sway held by traditional psychoanalytic thinking at mid-century, especially in American psychiatry, the psychogenic concept stole decades of meaningful psychological and biological research attention to the topic of autism, bringing enormous pain to families and no practical therapy or support for autistic people themselves.

The only good thing that can be said about the dominance of the “refrigerator mother” theory is that it finally lost currency, roughly around the time that steps were taken to codify a valid, science-and-data-based autism diagnosis in the American Psychiatric Association’s *Diagnostic and Statistical Manual of Mental Disorders* (DSM). In itself, however, this effort turned into yet another endless deliberation, spanning four decades (the late 1970s to the present), during which the successive working groups of experts recruited to validate autism’s definition from one DSM edition to the next repeatedly moved the boundary lines – sometimes jarringly.

To some extent, the zigzags reflected the fact that fresh data on autism was coming in all the time, shedding new light on the disorder, and legitimizing revisions. But each update (and they tended to be significant) reflected something else: a negotiation. By design, the expert working groups represented diverse points of view, whose members brought to the table their own distinctive frameworks for thinking about autism. These were shaped by their training (psychiatry or

psychology), by the professional milieus in which they worked (numerous regions of the world were represented), and especially by each person’s own interactions with autistic people either as researcher or clinician (itself an important distinction, though many of the recruited experts were both). Inevitably, though, diversity meant disagreement, and consensus rarely meant unanimity. To a degree that might surprise the lay observer, the evolving definition of autism – at least as it appeared in successive editions of the DSM – reflected a debate and a vote and an outcome influenced by which people in the room possessed the better powers of persuasion.

A case in point: The radical overhaul that autism’s diagnostic criteria underwent between 1980 and 1987.

DSM-III, which appeared in 1980, marked the first time autism was addressed in *any* DSM (3 years after it was listed in the World Health Organization’s International Classification of Diseases). DSM-III used a name that closely tracked what Kanner came up with 36 years earlier – “infantile autism” – placing it under the category “pervasive developmental disorders,” with the diagnostic code number 299.00. At a mere 70 words long, its tightly written criteria comprised three categories of behavior – lack of responsiveness to other people, deficits in communicative skills, and “bizarre responses to . . . the environment” – with a few sample behaviors listed for each category: for example, echolalia, in the communication category, and resistance to change, in the “bizarre responses” category.” No guidance was given on how to weigh these various behaviors against one another in deciding on a diagnosis.

The picture was dramatically different 7 years later, with the publication of an updated DSM-III-R (“R” for “revision”). Gone for good in 1987 was “infantile autism,” which was seen to cloud recognition that autism was lifelong. Also gone were a further four closely pervasive developmental disorders – for example, “infantile autism residual state,” which was supposed to account for individuals whose autistic behaviors lost some of their intensity over time. Now, DSM-III-R gave the

299.00 designation to an overhauled construct it dubbed “autistic disorder.” Designed to be both less restrictive than the old “infantile autism” and more reflective of developmental concepts (Szatmari 1992), it was framed around a diagnostic checklist that ran to more than 600 words. Again, symptomatic behaviors were grouped around three themes. This time, the categories were social interaction, communication (verbal and nonverbal), and a “restricted repertoire of activities and interest.” Also, a more deliberative diagnostic scheme was put in place. Now 16 specific behaviors were listed – such as “gross impairment in ability to make peer friendships” and “marked distress over changes in trivial aspects of environment, e.g., when a vase is moved from usual position.” These 16 behaviors were sorted among the 3 categories, and a rule was specified: diagnosis required a match with at least 8 of the 16 behaviors; at least 2 had to belong to the social interaction group; and at least 1 had to come from the other two groups.

This more operational approach to diagnosis was but one of that edition’s innovations in autism diagnosis. The other, even more sweeping one, was the creation of a controversial new “sister” diagnosis: “299.80, Pervasive Development Disorder Not Otherwise Specified.” The inelegant nomenclature belied a well-intentioned purpose – to provide a diagnostic landing spot to individuals who were near misses for the 299.00 diagnosis. These were defined as people displaying “qualitative impairment in the development of reciprocal interaction and of verbal and nonverbal communication skills,” but not to the extent, or in such combinations, that satisfied the checklist. Because this relatively vague definition made allowance for even quite mild symptoms, some would come to think of PDDNOS as a kind of “autism-lite” – especially compared to the “classic” autism Kanner had described. But this misunderstood the breadth and depth of impairment a diagnosis of PDDNOS might represent for many people who were given this diagnosis.

In the push and pull among experts, 1987’s *DSM* revision also represented a period of

ascendancy for one particularly compelling viewpoint on how to make sense of a phenomenon obvious to everyone: that autistic traits were remarkably variable in how differently they presented themselves in different people. This is the observation that gives rise to the oft-repeated aphorism, “when you’ve met one person with autism, you’ve met *one* person with autism.” In practice, the matter of how to interpret this heterogeneity has been an enduring source of tension in understanding what the word “autism” properly represents. One view holds that these differences likely indicate distinct and separate underlying syndromes – different autisms, so to speak – which should be delineated as such by splitting them off from one another. Both Kanner and Asperger, for example, stood among the so-called splitters, as both insisted adamantly that, despite some overlap, each had described a full syndrome distinct from the other’s. The splitter viewpoint was dominant in the 1980 *DSM*, where autistic traits were covered across those five different diagnoses.

But in the 1987 *DSM*, the “splitter” position lost ground to a competing perspective: that in nearly all cases, nearly all manifestations of autistic traits resulted from the same core mechanism or mechanisms, which happened to affect different people to different degrees. Those holding this view were often called the “lumpers,” for preferring to see past the differences and for preferring to “lump” together, to the maximum extent, the vast array of people displaying any measure of autistic behavior.

Prominent in this group was the British psychiatrist Lorna Wing, who played a singular role in crystalizing the concept she called the autism “spectrum,” the profoundly influential proposition that all autistic behavior – though representing a huge range of intensities, from profound to extremely mild, while operating independently of intelligence – is nevertheless rooted in the same syndrome of impairments, which she identified as a “triad of impairments.” This model, originally based on epidemiological studies Wing carried out with Judith Gould in the mid-1970s London, was not a dramatic departure from

previous formulations, specifying three areas of challenge: in social interaction, in the use of reciprocal language, and in what they called “social imagination,” where the ability to pretend play is an example of the last item.

Where she did break ground, however, was in the inclusiveness of her concept, which resisted the “splitters” tendency to want to draw sharp lines between, say, those who were called “higher” and “lower” functioning. Such distinctions, Wing wrote disapprovingly, have the “effect of excluding those who do not fit neatly into the categories.” It should come as no surprise that Wing served on the working group that developed the PDDNOS diagnosis in 1987, which was an excellent example of a “lumper”-type category and took a major step toward a “spectrum”-type conceptualization of autism. Wing, the mother of a daughter with autism, was motivated in part by a desire to justify support services for a far broader range of people than narrow diagnosis would allow. In time, the implementation of her ideas led to just that outcome.

But that is not to say that the diagnostic push and pull ever ended. Indeed, in 1994, it moved back toward “splitting” mode, slicing up the pervasive developmental disorders once again to include, in addition to autistic disorder, some of the previously “not otherwise specified” PDD conditions: Rett’s disorder, childhood disintegrative disorder, and, half a century after it was first described by its namesake, Asperger’s disorder.

It was Lorna Wing who had rediscovered Asperger’s work in the late 1970s and then popularized it in the 1980s. Wing’s involvement proved ironic, however, because her intention was never to see Asperger’s “autistic psychopathy” recognized as a standalone diagnosis. Rather, she brought attention to the Austrian’s work for the opposite purpose: she had wanted to suggest just how far the spectrum concept could be stretched, given that Asperger’s children were so different from Kanner’s, even as both employed “autistic” to describe some of their behaviors. The elevation of Asperger’s in 1994’s *DSM* was an outcome Wing neither desired nor anticipated, always

insisting there “no clear boundaries separating it from other autistic disorders (Wing 2005).”

Yet acknowledgment of Asperger’s syndrome by the *DSM* that year (and even earlier in the *ICD*) proved pivotal across multiple fronts. It quickly caught on with clinicians, becoming an increasingly assigned diagnosis, often employed, Wing herself believed, to spare parents the discomfort of hearing the word “autism.” The diagnosis also began to be given to adults – people who had grown up facing social challenges without the benefit of a diagnostic perspective in which to frame their difficulties. Finally, recognition of Asperger’s as “a form of autism” – a phrase the media often used – had important cultural impact, to some degree destigmatizing autism in general by association with often highly intelligent and articulate self-advocates who positively embraced their own diagnoses as central to their identities. Plays, books, and movies began to appear, centering sympathetically on the stories of people who more or less matched the diagnosis, while websites began appearing designed for, and later by, self-described “Aspies,” who expressed pride in the ways they were different from the population at large.

But then, in 2013, a new *DSM* appeared, and this one no longer included Asperger’s syndrome. Once again demonstrating the extreme malleability of such constructs, the team assigned to define the pervasive developmental disorders listened to the researchers and clinicians who had long complained that Asperger’s was actually a problematic concept, resistant to stringent criteria, and understood differently in different clinical settings – or, as one team member puts it, the diagnosis had proven “confusing and not terribly useful.” Asperger’s was dropped and so, too, was PDDNOS and all the other specified developmental disorders that had been in use for the previous two decades. Indeed, in vindication of Lorna Wing’s 35-year-old argument that autism represented a spectrum, a new formulation appeared in the latest *DSM*, using that term “299.00 Autistic Spectrum Disorder” (ASD).

Future Directions

ASD represented the apotheosis of “lumper” thinking, by aiming to eliminate all reference to sub-syndromes. In addition, the criteria aimed to be inclusive of nearly all individuals previously assigned any of the now-vanished diagnoses, as well as some who had earlier qualified for no diagnosis at all. As a result of this development, the number of individuals empowered to claim “I have autism” or “I’m autistic,” by reference to how professionals in the field defined the term, reached an all-time high and is estimated to account for roughly 1 percent of the human race.

At least, for now. It is by no means clear that the all-encompassing spectrum will remain the last word in how autism is perceived and addressed. The lack of certainty about the underlying drivers of autistic behaviors remains as persistent as ever, while the interplay of subjective and even competitive perspectives in the diagnostic process remains as problematic as ever. It is entirely possible that genetic and other biomedical research may, ultimately, discover the existence of multiple pathways to the same still rather amorphous grouping of the behaviors that are used to identify autism. This could once again revive interest in delineating multiple syndromes “hidden” within the spectrum, each with its own instigator, internal mechanisms, and treatments. If that were that to happen, the ever-evolving debate about what we all mean when we say “autism” would, without a doubt, enter yet another new round.

Hoarding in Youth with Autism Spectrum Disorders

Definition

Before publication of the DSM-5, hoarding was conceptualized as a symptom of obsessive-compulsive disorder (OCD). However, research findings has led to the reclassification of pathological hoarding, known as hoarding disorder (HD), into a separate diagnosis from OCD with primary diagnostic criteria encompassing (a) a persistent difficulty discarding possessions, (b) distress associated with discarding items, (c) the accumulation of clutter, and (d) clinically significant distress/impairment (American Psychiatric Association 2013). The age of onset of compulsive hoarding ranges from 11 to 15 years old, but symptoms may not become clinically significant until adulthood (Tolin et al. 2010). The overall prevalence rate of HD ranges from about 1.5 to 5.8%, though most research has studied adults (Nordsletten and Mataix-Cols 2012; Timpano et al. 2011).

Hoarding behaviors may be common among youth with autism spectrum disorders (ASD) for three reasons. First, executive functioning deficits (e.g., in planning, attention, task completion, organization) are associated with both childhood (and adult) HD and ASD and could contribute to hoarding behaviors. High rates of HD have been found with ADHD (Fullana et al. 2013; Hacker et al. 2016), which is comorbid in 28.2–30.6% of cases with ASD (Leyfer et al. 2006; Simonoff

et al. 2008). Executive functioning difficulties may be associated with impulsive collecting/acquisition, difficulty organizing and discarding possessions, and planning to throw away objects in the future (Storch 2011a). Second, the repetitive and restricted interests associated with ASD may influence incidence of hoarding behaviors (Storch et al. 2016). For instance, a child with ASD, who has a strong interest in geology, may attempt to acquire rocks and related items and have difficulty discarding those items. Third, the overlap between ASD and anxiety disorders in children and adolescents may increase the risk or severity of HD. Anxiety disorders are often maintained by safety cues (e.g., stuffed animals, music, caregivers) that children or adolescents use to mitigate the anxiety they experience from aversive stimuli (Storch et al. 2016). As a result, children and adolescents may develop personal attachments to these objects that lead to strong emotional reactions when having to discard or separate from them.

Assessment

In children and adolescents, behaviors meeting criteria for HD must first be differentiated from developmentally appropriate behaviors (i.e., hobbies, collections) as well as symptoms associated with ASD (e.g., the collection of objects due to restricted interests or repetitive behaviors). To aid in this differentiation, Storch et al. (2011b) note that children who hoard often collect objects such as boxes, paper clips, school papers, stickers, items from nature (i.e., rocks), or erasers. In addition, children and adolescents who hoard may develop strong emotional attachments to objects by assimilating them into their personal identities (Plimpton et al. 2009). These attachments are often strong enough to cause significant distress about hurting or damaging specific items, thereby preventing children or adolescents from discarding them. Another distinguishing feature is that among children and adolescents who hoard, removing or throwing away hoarded objects typically leads to negative emotional/behavioral reactions (Plimpton et al. 2009).

To assist with diagnoses and treatment, a multimodal, multi-method assessment that identifies hoarding symptoms and comorbidities is recommended for children with hoarding behaviors (Frost and Hristova 2011). An interview with a trained clinician who has experience in working with children with ASD is the cornerstone of assessment. Currently, the only developmentally appropriate measure is the Child Saving Inventory (CSI; Storch et al. 2011a), which is a 23-item, parent-rated scale assessing four domains: discarding, clutter, acquisition, and distress/impairment. Beyond this, broadband measures that include items that assess hoarding may be helpful (e.g., Achenbach 1991) as well as the Children's Yale-Brown Obsessive-Compulsive Scale (CY-BOCS; Scahill et al. 1997), which includes a single item assessing hoarding symptom presence, as well as overall severity.

Treatment

Few studies have been conducted with children and adolescents experiencing comorbid ASD and HD. Although not among children with ASD and HD, case studies have reported success in childhood HD when using a parent-focused behavioral intervention involving contingency management. For instance, Ale et al. (2014) demonstrated that parental involvement played an integral role in treatment to generalize skills to multiple settings, to increase treatment gains, and to provide encouragement. In his case study on a 10-year-old with OCD and hoarding behaviors, McKay (2016) first utilized an assessment battery containing the CY-BOCS and conducted a functional assessment to provide more detail about the patient's hoarding behaviors. When the functional assessment revealed hoarding that was narrowly focused on objects related to academics (e.g., schoolwork from years ago), he implemented cognitive-behavioral therapy with exposure and built a fear hierarchy to help the patient systematically address her hoarding behaviors. Similar to Ale et al. (2014), McKay (2016) also highlighted the need for parent-provider collaboration and reward systems to boost motivation and treatment compliance. Preliminary data are also available from a

study focused on cognitive-behavioral therapy (CBT) for anxiety among youth with ASD. Storch et al. (2016) conducted exposure-based CBT with 26 youth with ASD and a comorbid anxiety disorder over 16, 90-minute sessions. Although the treatment was focused on anxiety broadly, core hoarding symptoms across several domains (e.g., distress, clutter, difficulty discarding, and acquiring items) decreased following intervention.

Future Directions

There are several areas highlighted for future work. First, large epidemiological studies may elucidate the role of genetics and heritability in ASD and HD. As a result, more accurate prevalence rates will narrow comorbidity estimates and provide researchers and practitioners with more accurate base rates for their diagnostic decisions. Second, treatment protocols for HD in youth are needed, as well as how to adapt such interventions to be individualized to working with youth with ASD. Third, further development and evaluation of rating scales to supplement the CSI will improve assessment practices and increase diagnostic accuracy. Finally, the literature could benefit from studies investigating shared etiology in HD and ASD that could provide a developmental/prospective course of such symptoms.

Holliday Willey, Liane

Adam Feinstein

Autism Cymru and Looking Up, London, UK

Short Biography

Liane Holliday Willey, Ed.D. (born 1959), is a best-selling American author, educator and public speaker. She was diagnosed with Asperger's syndrome in 1996. She coined the term "Aspie" in her 1999 autobiography, *Pretending to be Normal: Living with Asperger Syndrome*. Dr. Willey has authored several other internationally best-selling books, all published by Jessica Kingsley Publishers, including *Asperger Syndrome in Adolescence: Living with the Ups, the Downs and Things in Between* and *Asperger Syndrome in the Family: Redefining Normal*. Her latest book is *Safety Skills for Asperger Women: How to Save a Perfectly Good Female Life* (2011).

Dr. Willey has contributed to many additional books and journals and is currently the senior editor for *Autism Spectrum Quarterly*. In addition to her numerous interviews on national and international television and radio, her life story was an

inspiration for the film *Normal Folk*, currently in preproduction, and the feature film *Adam*, as well as the focus of the video *Asperger Syndrome: Crossing the Bridge* with Dr. Tony Attwood.

Dr. Willey believes the Asperger's syndrome community is a wonderfully rich world that is populated by some of the most interesting and incredible individuals on the planet and she is exceptionally proud to be a part of it. She is the founder of the Asperger Society of Michigan.

Home Schooling in Autism

Noah Remnick

Ezra Stiles College, Yale University, New Haven, CT, USA

Definition

The 1990 Individuals with Disabilities Education Act (IDEA) promotes students being placed in the least restrictive environment for educational purposes, and that has encouraged the widespread

placement of students with autism spectrum disorder (ASD) in brick-and-mortar schools – public and private, general education and special education, and integrated and specialized. The heterogeneity of the ASD population complicates this task because while certain core communications deficits affect most individuals with ASD, the levels of intensity and interference vary widely, as do the particular constellations of symptoms that any person manifests. The characteristics of students with ASD, and the lack of preparedness of schools to deal with them, have had a negative impact on the experiences of many of these students in school settings, with problems encompassing poor academic performance, bullying, and strained social relationships. For many ASD students, homeschooling – where there are fewer conflicts and greater individualization – could provide a more appropriate and successful setting for learning.

Homeschooling is an option available to all students, and families choose this alternative educational setting for a variety of reasons, including religious, professional, financial, medical, social, and philosophical. Homeschooling programs can be taught by parents, by joining in cooperatives with other families, by computer, or by hiring professional pedagogues. In the case of students with ASD, those who function at a higher intellectual level can usually avail themselves of the full range of homeschool implementation choices. But students with more severe manifestations of ASD generally require trained, experienced clinicians, special education teachers, and therapists to carry out an effective individualized home-based education plan that fosters meaningful academic, social, and behavioral progress.

Historical Background

The Centers for Disease Control and Prevention (CDC) reports that 1 in 68 children in the United States has been diagnosed with ASD (Baio 2014), and all of those children are entitled to a Free and Appropriate Public Education (FAPE), as dictated by the 1990 Individuals with Disabilities Education Act. Prior to 1975, school districts could

decide that a child with a disability was too difficult, or too expensive, to educate. In 1970, for example, government statistics show that only 1 in 5 children with disabilities attended public schools, with school districts regularly refusing with impunity to embrace children who were, among other disorders, deaf, blind, and mentally retarded. Most children with special needs were educated in private schools paid for by their families, or they were institutionalized (United States Department of Education, Office of Special Education and Rehabilitative Services, pamphlet date unknown). In 1975, however, Congress passed the Education for All Handicapped Children Act, enshrining the rights of all children to a government-funded education, no matter their circumstances. The law was expanded and updated in 1990 with the passage of IDEA and further amended in 2004. Today, the vast majority of students with disabilities, including those with ASD, are taught in brick-and-mortar schools (Fleury et al. 2014; Chen and Schwartz 2012). The schools are public and private, special education, and mainstream. Some ASD students learn alongside typically developing peers, in some cases with assistance from special educators or paraprofessionals for all or part of their days.

IDEA demands that students be allowed to learn in the least restrictive environment, a rule intended to counteract the forced warehousing of students with disabilities that happened in decades past. The process for deciding the appropriate placement for any student is complex. What seems restrictive for one person might be more liberating and productive for another. For some students, even those with high IQs, being in a traditional school involves a level of sensory overstimulation, conformity to extensive rules, and continuous social interaction that could impede their ability to make meaningful educational progress. Indeed, current methods for dealing with ASD students show limited long-term success. People with ASD rank third from the bottom in college enrollment among 11 disability categories. Meanwhile, only 37 % of young adults with ASD are employed, and most of them only in part-time jobs without benefits (Fleury et al. 2014). Ironically, those with ASD who are not

intellectually compromised have triple the chance of being unemployed and unengaged in leisure activities with their peers, compared with young adults who have ASD coupled with intellectual disabilities (Fleury et al. 2014). This statistic is especially disconcerting because the overwhelming majority of people diagnosed with ASD has milder manifestations of the disorder (Van Bergeijk et al. 2008) and presumably should be able to attain greater success in the classroom and beyond. In general, minimal research has been done on this population as it moves past young adulthood; still, while these shards of data are limited, they offer a bleak window onto the prospects for ASD adults.

Current Knowledge

Academic Barriers to School Success for ASD Students

The characteristics that define a person as having ASD render school a treacherous system to navigate. In all its iterations, autism is primarily a communication disorder that undermines a person's capacity to interact with others appropriately (Van Bergeijk et al. 2008). People with ASD have, to varying degrees, a compromised ability to observe, imitate, and apply new skills – all essential components of acquiring knowledge. They typically exhibit rigid and repetitive behaviors that interfere with learning and dealing with other people, whether fellow students, teachers, or school staff. Their auditory and visual processing speed is often slow and difficult to manage (Fleury et al. 2014; Van Bergeijk et al. 2008). Their conversation skills are severely constrained – at the most affected edge of the spectrum in basic expressive and receptive language and even in quality of speech production, and at the higher functioning and Asperger syndrome (AS) edge, in their dexterity in reciprocating and empathizing with another in conversation (Fleury et al. 2014; Van Bergeijk et al. 2008; Volkmar and Klin 2001).

The list of scholastic roadblocks runs on. While many ASD students have good decoding skills in reading, they often have poor

comprehension, in part because of their difficulty in assuming the perspective of another (Fleury et al. 2014). In writing, poor fine motor skills interfere with the physical ability to produce words on paper or to type, a process further frustrated by weak visual motor speed and coordination. In terms of content, trouble with empathy and perspective gets in the way of composing creatively and with clarity (Fleury et al. 2014). And one of the most complex skills needed to succeed in a school environment is the organization born of executive function processes that most people with ASD lack (Rosenthal et al. 2013).

Over the last few decades, schools have relied more upon team learning and projects, a looming obstacle for ASD students compromised in their pragmatic and social language abilities, and their facility at reading social cues well enough to join forces for a group endeavor (Durkin and Conti-Ramsden 2007). Moreover, as focus shifts from individual students with ASD to the group, executive functioning deficits can seriously undermine their ability to retain information and contribute meaningfully to the collaborative work (Rosenthal et al. 2013).

People with ASD also have a high incidence of other psychiatric and neurological conditions that exacerbate the autism itself and can inhibit learning. Common comorbid disorders for people with ASD include attention deficit hyperactivity disorder (ADHD), anxiety, depression, grapho-motor deficits, seizures, and intellectual disabilities (Van Bergeijk et al. 2008). Indeed, Van Bergeijk et al. (2008) note that 65 % of people with ASD have anxiety and/or depression (p. 1361), conditions that on their own would impede any student's ability to cope in the fast-paced academic and social world in a school and that can overwhelm a person already reeling under the weight that ASD deficits impose.

Imagine for a minute the ASD student in a school building bustling with children racing to class, returning from a football game, or practicing for the annual musical. The aroma of tacos and pizza wafts from the cafeteria – a crowded room abuzz with laughter, conversation, and song. In addition to all the intellectual and organizational

skills he lacks, the ASD student is also sensitive to sudden noise and movement, keenly aware of sights, sounds, and smells he cannot control.

These deficits are obstacles to every facet of learning in a school filled with other pupils, whether those students share one's disabilities or are free of them. Since every person with ASD has a different cluster of symptoms, behaviors, challenges, strengths, and compensations, schools are stymied in their efforts to create comfortable environments for all. The heterogeneity of the population makes it impossible for schools to develop an easy, "off-the-rack" approach to deal with ASD students. Furthermore, behavioral problems can deluge the child and staff, interfering with the learning not only of the individual with ASD but of the entire class as well. Given the staggering demands, there are generally insufficient academic and behavioral support services to foster reliable success for ASD students in a school setting (Van Bergeijk et al. 2008; Catherine Lord, personal communication, June 25, 2014).

One significant measure of the subpar school options being offered to students with ASD is the rise in litigation by dissatisfied parents seeking reimbursement for nonpublic school programs for their children. Parents of children with ASD are 10 times more likely than parents of children with other disabilities to sue school districts to force fulfillment of FAPE, and they account for about a third of all cases filed overall (Zirkel 2001). This disproportionality is due in part to the complexity and severity of ASD but also speaks to the failure of school districts to offer the proper comprehensive services and environment necessary to educating a student with the disorder.

Social Barriers to School Success for ASD Students

By their nature, schools and classrooms are not just centers of scholarship; they are communal organizations that depend on the kind of compromise and cooperation that eludes most people with ASD because the interfering symptoms and behaviors are the root expression of the neurological condition itself. Poor social skills are a hallmark of people all along the autism spectrum

(Volkmar and Klin 2001; Durkin and Conti-Ramsden 2007; Van Bergeijk et al. 2008). When someone has poor social competence and lagging academic skills, the two deficiencies feed off one another in a way that produces negative outcomes in both spheres (Welsh et al. 2001). There is a “chicken-and-egg” debate about which is the primary determinant of the other: some research suggests that academic failure leads to students being ostracized socially, while other research points to low social status as a source of low academic achievement. Whether or not a definitive cause and effect can be established, it is clear that over time, the two influence one another and are mutually predictive. Welsh et al.’s (2001) longitudinal study found that “academic competence exerts a significant influence over social competence consistently,” with the negative correlate being true as well (pp. 477–478).

This finding bodes ill for students with ASD studying in traditional schools, where managing social relationships with teachers, fellow students, and staff is enmeshed in all daily activities. The need while in school to respect boundaries, to empathize with others, to be flexible, and to read social cues thwarts people with ASD, who lack such emotional intelligence when it comes to dealing with peers and with adults who work in schools. Even the most academically capable students with ASD, namely, those with Asperger syndrome, suffer from poor social skills, sensory issues, and pragmatic language deficits (e.g., lack of reciprocal conversation and perseverative topics) that compromise their overall performance and well-being in school (Church et al. 2000). The inability to communicate appropriately through language circumscribes a child’s ability to form close relationships. When combined with impaired social cue reading and inconsistent self-regulation, ASD students are limited in their ability to access the friendships theoretically available in a school setting (Durkin and Conti-Ramsden 2007). High functioning students with autism, although unburdened by comorbid intellectual disabilities, can be so rigid and rules-bound that they often, for example, tattle on their classmates, causing further social alienation (Church et al. 2000). As one parent lamented

about his son, “He doesn’t have weak social skills, his social skills are non-existent!” (Church et al. 2000, p. 18).

The opportunity to socialize with peers, to learn from their example how to behave appropriately, is often cited as a critical potential benefit for ASD students in attending schools. Reality, however, does not commonly live up to such expectations, according to the literature and interviews with experts in the field. For ASD students in specialized schools, peers often model maladaptive behaviors – such as tantrums and flapping – that should not be imitated but frequently are. For those in mainstream schools, acceptance is not easily forthcoming. In school, where one sits, the foods one eats, the clothes one wears, all send myriad silent signals that most ASD students cannot interpret. “The greatest lesson of childhood is not reading, writing or arithmetic,” said Dr. Orrin Devinsky, a neurologist and the director of NYU’s Comprehensive Epilepsy and Seizure Center, who has many patients with ASD since seizures are a common comorbid condition with autism (O. Devinsky, personal communication, June 26, 2012). “For most of human evolution, we acquired language without teachers, just older individuals who spoke. Socialization is the key of childhood. The lesson. But for ASD kids, they are with other ASD kids and the lesson of socialization is a bizarre and foreign one – the role models are skewed to watching kids with self-injurious behaviors, tantrums, lack of eye contact, etc. For those who get some mainstream time, there are great benefits (more normal social peers) but also cases where kids can be insensitive and cruel.”

Media stereotypes of people with autism coupled with ignorance reinforce the social sand traps that the disorder itself sets. Typical children generally reveal unfavorable attitudes toward peers with autism when they are shown pictures and film clips of them. Although some research has shown that these negative associations improve when the children are given explanations for the aberrant behavior – including the lack of eye contact and repetitive motions, such as arm flapping – other research does not (Campbell et al. 2005). This negative stereotyping not only influences students but also affects the views of their

parents, of teachers in the classroom, and of the general school staff. In some cases, students engaged as peer mentors can help bring an ASD classmate into the social fold. This intervention tends to work best when the mentors are so-called high-status children, whose leadership skills and popularity influence classroom social dynamics. But the research indicates that acceptance of the ASD student can be fleeting because it occurs due to a desire by the other students to please the mentors, not a genuine change in their attitudes. The mentors themselves often do not change their attitudes either, nor do they always act out of altruism; rather, they take on the role generally because they perceive that being an advocate for a disabled peer will enhance their own leadership ranking (Campbell et al. 2005).

Few typical students are willing or able to become a genuine protector to their ASD classmates. Most students simply ignore them. But some seize on the ASD students as easy prey for ostracizing and maltreatment. Having low status and diminished social skills leaves many students with ASD particularly vulnerable to bullying in school, as targets are often awkward, marginalized young people with poor peer relationships – characteristics common to ASD students (Cappadocia et al. 2011; Chen and Schwartz 2012). Parents, students, and teachers report high levels of victimization of students with ASD by fellow classmates. About 40 % of students with ASD report being bullied, according to Dr. Fred Volkmar, director of the Yale Child Study Center; for those with a comorbid condition, that number rises to roughly 75 % (F. Volkmar, personal communication, June 29, 2014). Research by Cappadocia et al. in 2011 put the percentage of ASD students who are victimized as possibly higher, with 77 % of parents interviewed reporting that their children with ASD had been bullied at school in the previous month (Cappadocia et al. 2011). Such victimization has serious negative consequences for the target from academic, behavioral, social, physical, and psychological perspectives (Chen and Schwartz 2012; Sterzing et al. 2012).

School bullying is difficult to root out, however, because it involves a complex web of social interactions, rather than a singular act of cruelty

(Cappadocia et al. 2011). Bullies are generally adept at choosing moments of attack that evade adult detection, and students with ASD often lack the verbal skills to report their own victimization. Even when they are able to identify an attacker, ASD students – and, indeed many typically developing students who are targets – overwhelmingly fail to report being abused because they are ashamed, fear retribution, or are too socially oblivious to realize they have been humiliated or shunned (Campbell et al. 2005; Chen and Schwartz 2012). Moreover, ASD students generally do not have the self-advocacy skills to confront their tormentors or a safety net of peers to look out for them and comfort them when they are victimized (van Roekel et al. 2010). So instead of learning from typical peer models how to socialize appropriately, ASD students generally pull back from social interactions, or worse: Sometimes they imitate the bullying behaviors and target others – either out of anger, or ignorance (Chen and Schwartz 2012). Indeed, many people with ASD are emotionally labile and even abusive (Church et al. 2000), characteristics that make them especially susceptible to the invidious lure of bullying others.

Even when ASD students avoid the perils of bullying – as both perpetrators and, more often, victims – the structure of the school environment underscores that they are different from their peers. They labor under labels that regularly remind them – and their classmates – that they stand apart. They are the ones with special educators or paraprofessionals shadowing them in the classrooms and on the playing fields, the ones who get extra time on tests, or have augmentative communication devices, the ones who get pulled out of class for therapy. Throughout the school day, the emphasis is on their differences, not their similarities – a dagger to the self-esteem of those special education students intellectually and emotionally aware enough to take note (Ensign 2000).

Future Directions

There is scant peer-reviewed or scholarly research and literature on homeschooling students with

ASD. There are some books on the subject, but they are almost entirely how-to manuals, with some incorporating personal stories. None contains any systematic research. As such, in order to hypothesize how a similar home learning environment might work for students with ASD, extrapolating from the professional literature that examines the homeschooling experiences of less compromised students, for example, those with learning disabilities or ADHD, is required. In a 9-year longitudinal study of homeschooled special education students, Ensign (2000) revealed that learning in a home environment freed such students of the stigmas and stereotypes that inhibited their education and socialization in traditional schools – mainstream and specialized. Ensign noted research that showed “the culture of school orchestrated labeling and disabling” students with special needs (p. 149), a plight common to ASD students educated in schools, while being at home minimized or eliminated those stressors.

Duvall led two different investigations into the homeschool experiences of children with other interfering disorders – one in 1997 of students with learning disabilities and one in 2004 of students with ADHD (Duvall et al. 1997, 2004). Both studies showed that students with special needs flourished in the calmer, more attentive home environment and that they engaged significantly more with their work than they had when they were in school, making greater reading and math gains than their peers with similar issues who attended the public schools. Although small in size, both studies indicated that homeschooling provides an advantage to students who need more intensive instruction.

In her study, Ensign (2000) found that the success emanated from the fact that parents were able to create an educational milieu at home that emphasized the strengths of special students, rather than their deficits, and that encouraged excellence based on individual aptitude and interests. Unbound by the dogma of most state rules and regulations, the parents (or their surrogate teachers) could give extra time for areas of struggle and encourage acceleration in areas of promise (Ensign 2000). Dr. Devinsky said he has observed

that for ASD students with heightened sensitivities and circumscribed capabilities, a homeschool program often offers the only appropriate environment for fostering progress and forestalling regression. “The greatest benefits of homeschooling are removing a child from a chaotic environment where their mind may be hyperstimulated and so overwhelmed they shut down or explode as their major behavioral patterns,” he noted (O. Devinsky, personal communication, June 26, 2014). Furthermore, he stated that homeschooling students with ASD “removes them from negative peer behaviors and models (they don’t learn to spit or hit their heads) and can remove them from a chaotic environment to a more nurturing one, and can allow a more relaxed and individually targeted program” (O. Devinsky, personal communication, June 26, 2014).

Creating a homeschool program for typically developing students is cumbersome; for ASD students with the need for highly specialized therapies and instruction, doing so is especially costly – financially and in the burden it places on the student’s family. It puts added pressure on the parents to earn enough money to cover the significant expenses such programs impose and burdens them with managing its details (F. Volkmar, personal communication, June 29, 2014). Since IDEA guarantees a free and appropriate public education to all children, when the school district fails to provide an ASD student with an education that is appropriate to his or her unique needs, parents often construct a program on their own and then litigate to receive reimbursement to fulfill the promise of “free” embedded in FAPE. Not all families have the intellectual, emotional, and financial resources to sue their school districts. The process can be long and success is not assured. The responsibility to ascertain what their ASD student needs educationally – and to arrange, monitor, and fund the program – falls on the shoulders of parents already exhausted by the responsibility of caring for a challenging child. “Most families do not have situations in which students could learn at home – they do not have enough space and often do not have someone at home who can coordinate various educational activities,” reported Dr. Catherine Lord, Director

of the Center for Autism and the Developing Brain in New York, and one of the creators of the Autism Diagnostic Observation Schedule (ADOS), a leading assessment tool for diagnosing ASD (C. Lord, personal communication, June 25, 2014). But faced with inadequate programs in their local schools, parents of students with ASD are increasingly crafting individualized homeschool programs for their children outside of the public or private school system, and they are increasingly suing for reimbursement of the substantial costs (Zerkel 2011).

For many students, the barriers to learning and socializing in brick-and-mortar schools can be overcome, and they can achieve success. But the literature that does exist and the experiences of experts in the field suggest that many students could do much better academically, behaviorally, socially, and psychologically in an individualized homeschool setting. At home there are no learning disabilities, there is only learning. As such, this approach should be studied in a comprehensive and methodical way to measure its potential for improved academic, post-academic, and social outcomes for students with ASD.

Home-Based Programs

Svein Eikeseth

Department of Behavioral Science, Oslo and
Akershus University College, Lillestrøm, Norway

Definition

Home programs to provide treatment for young children with autism were pioneered by O. Ivar Lovaas in the 1970s and 1980s. A home program focuses on remediating the children's delays in communication and social and emotional skills and emphasizes the integration of these children with typical peers in mainstream community settings. Principles derived from laboratory and applied research on learning psychology are used to teach developmentally appropriate and functional skills.

As described by Green and colleagues, a home program has the following characteristics:

1. Treatment is individualized and comprehensive, addressing all skill domains.
2. Typical developmental sequences derived from data from developmental psychology guide the selection of intervention goals and short-term objectives.
3. Multiple behavior analytic procedures are used to teach new skills and to reduce interfering behavior (e.g., differential reinforcement, prompting, discrete-trial teaching, natural environment teaching, activity-embedded trials, task analysis, and others).
4. One or more professionals with advanced training in applied behavior analysis and advanced training in behavioral intervention with young children with autism direct and supervise the intervention.
5. Parents serve as active co-therapists for their children.
6. Intervention is initially delivered in one-to-one sessions, with gradual transitions to small-group and large-group formats as a child progresses.
7. Intervention begins in the home and is carried over into other environments (e.g., community settings), with gradual, systematic transitions to preschool, kindergarten, and elementary school classrooms when children develop the skills required to learn in those settings.
8. Intervention involves intensive, year-round teaching, including 20–40 h of structured sessions per week plus informal instruction and practice throughout most of the children's other waking hours.
9. In most cases, a child receives two or more years of intervention.
10. Most children start intervention in the pre-school years.

Home programs are usually associated with early intervention programs, especially Early and Intensive Behavioral Intervention (EIBI) for children with autism. The use of home programs to deliver EIBI originates from the Lovaas

approach (the UCLA Model) and the UCLA Young Autism Project.

Historical Background

Home programs have roots in applied behavior analytic (ABA) interventions that were first introduced for children with autism in the early 1960s. Home programs originated a decade later as a result of finding from the first long-term follow-up study of ABA interventions for children with autism (Lovaas et al. 1973). Twenty children with autism participated. After 12–14 months of behavioral treatment, stereotyped behaviors including echolalia decreased, and appropriate speech, appropriate play, and social nonverbal behaviors. Some of the children were discharged to a state hospital while others remained with their parents, who had received parent training. Follow-up assessments one to four years after the end of treatment showed that children whose parents were trained to carry out the behavioral treatment continued to improve, while children who were institutionalized regressed. After a brief reinstatement of the behavioral treatment, however, the institutionalized children recouped some of their original gains.

From the 1973 follow-up study, Lovaas made several important observations that led him to develop the home program. First, the youngest children in the 1973 study appeared to make the greatest gains; hence, he focused on providing treatment to toddlers and preschoolers with autism and regarded home as the most developmentally appropriate setting for children. Second, treatment effects in the 1973 study were situation specific. As a result, treatment was moved away from a hospital or clinic setting and into the children's everyday environments (including the home). Third, some parents became skilled teachers of their children and became the best allies in helping accelerate and maintain treatment gains. Provision of treatment at home maximized opportunities for parental involvement.

Following the 1973 study, a home program became an integral part of EIBI services, especially in the UCLA Young Autism Project. In 1987, Lovaas (1987) reported an evaluation of a group of 19 children with autism who participated in a home-based EIBI program for 40 h per week for a minimum of 2 years. This report indicated that, after treatment, the average IQ of children in home-based EIBI programs was more than 30 points higher than 40 children in comparison groups and that the children were much more likely to be included in general education settings. Subsequent reports also showed that children in home-based EIBI made large gains relative to comparison groups (e.g., Cohen et al. 2006; Sallows and Graupner 2005; Smith et al. 2000).

Since Lovaas's (1987) report, home programs have become increasingly accepted as an intervention for young children with autism. They are a common feature of EIBI services that emphasize ABA teaching methods. They are also a component of other treatment models such as the Developmental, Individual Differences, Relationship-Based Approach (DIR).

Rationale or Underlying Theory

In a home program, an underlying rationale is that the treatment environment should differ as little as possible from the typical learning environment in order to help the child with autism transfer skills to the typical environment and function more successfully in that setting. Also, active involvement of the parents and other family members is a crucial component of treatment success.

Goals and Objectives

A home program is usually set up for delivering an EIBI curriculum such as the curriculum described in the sections on the UCLA Young Autism Project and Lovaas approach. The curriculum is individualized based on each child's needs and stages of development that typically developing children go through.

Treatment Participants

The home program was developed primarily in EIBI models for children with autism who have mild to moderate intellectual disability and are under the age of 42 months at treatment onset. However, it has also been evaluated with children with more severe intellectual disability. Several studies have examined relations between intake variables and outcome measures. Meta-analyses have indicated that the most robust finding to date is a strong positive correlation between treatment intensity and outcome.

Treatment Procedures

Typically, 30 to 40 h per week of one-to-one instruction is provided in the child's home by the parents and trained therapists. If the child is younger than 3 years of age, 20 to 30 h per week of instruction is more common. Initially, most of the teaching is carried out in a discrete trial format, which is a highly structured teaching procedure used to establish a number of important skills, including cognitive skills, communication, play, social, and self-help skills. Also, time is devoted to play and other structured activities, in which the child has opportunities to use skills acquired during discrete trial teaching (e.g., labeling toys or taking turns with the tutor during a game) and learning new skills in situations where they naturally occur (e.g., learning names of new toys, acquiring motor skills while playing soccer, or practicing dressing before going out for community trips).

After the child has acquired important communication, play, and social skills, play dates with typical peers become a priority for the home program. The tutor facilitates mastered activities for the child and peer (e.g., conversation, pretend play with toys, or turn-taking games) and encourages the peer to engage the child.

After the child is able to sit still and attend to a teacher during small group instruction, and has learned prerequisite communication, preacademic (e.g., cutting, pasting, drawing, doing puzzles)

play, and social skills, the child is mainstreamed in a regular preschool. At that time, there is a gradual decrease in number of one-to-one hours at home and a gradual increase in time spent in school. Trained tutors accompany the child to school functioning as a classroom aide.

Efficacy Information

Since the original study by Lovaas (1987), there have been a number of other studies on home-based EIBI programs. Recently, a number of effect-size studies have been published, and several report large effect sizes for IQ and adaptive functioning.

While researchers generally agree that the results of studies have generally been positive, there remains controversy about the scientific quality of the studies, and many have called for additional research with improved research designs. In addition, direct comparisons between home programs and center-based or school-based programs have not been conducted. Thus, it remains unclear to what extent the provision of treatment at home contributes to overall outcomes.

Outcome Measurement

The most common outcome measures used are IQ, language, and adaptive functioning. The Bayley Scales of Infant Development and the Wechsler Intelligence Scales (WIPPSI or WISC) are the most common IQ tests.

The most widely used instrument to assess language is the Reynell Developmental Language Scales, but due to their severe delays in communication, many participants fail to achieve basal on the Reynell at intake.

To assess adaptive behavior, the Vineland Adaptive Behavior Scales is used.

Some studies have also assessed other domains, such as maladaptive behavior (using the maladaptive scale from Vineland Adaptive Behavior Scales, the Personality Inventory for

Children, and the Child Behavior Checklist), school performance (using the Woodcock-Johnson III Tests of Achievement), and changes in diagnosis (using the Autism Diagnostic Interview-Revised (ADI-R).

Qualifications of Treatment Providers

There are currently no established programs to certify professionals to become competent home-program therapists or home-program supervisors. Practitioners of the home program indicate that, to become a competent therapist, individuals should obtain a bachelor's degree in psychology, education, or social work, with coursework applied behavior analysis, developmental disorders, and child development. In addition, they require therapists to work at least three months hands-on with a child in an apprenticeship with a trained therapist. At the end of this training, the therapist must be able to apply the behavioral principles correctly during one-to-one teaching.

To become a supervisor, Lovaas and colleagues have required the practitioner to be an experienced home-program therapist and hold a master's degree that includes graduate courses in applied behavior analysis, developmental disorders, and child development. In addition, the supervisors must learn how to conduct staff training, develop and individualize the child's curriculum, and work with families. These skills can be learned through working in an apprenticeship with a competent home-program supervisor, and by studying available teaching manuals, evidenced-based parent training programs, and typical development. Finally, the supervisor should be supervised by a Ph.D. level clinical psychologist specializing in the home program.

Homework/Assignments, Modifying

Kara Hume

University of North Carolina, Chapel Hill,
NC, USA

Synonyms

[Homework/assignments, modifications](#)

Definition

Changes in the content, instructional level, or performance criteria provided for students with autism. Modifications to homework or in-class assignments are implemented to allow active participation in classroom activities while also ensuring that IEP goals are addressed and successfully accomplished. Common modifications for individuals with ASD include the use of picture symbols and/or visual supports such as social stories; audio and video recordings in place of/in addition to text; shorter or alternate assignments such as outlines or projects in place of lengthy essays or written reports; accessing technology such as calculators, personal digital assistants (PDA), or spell check programs during homework/assignments;

incorporating motivational procedures; alternative assessments; and adjusted grading standards.

Hug Machine

Temple Grandin

Department of Animal Sciences, Colorado State University, Fort Collins, CO, USA

Definition

I developed the hug machine, also called the squeeze machine, to calm my anxiety when I was a teenager. I am a person with autism, and when I entered puberty, I was in a constant state of anxiety and panic attacks. When I visited my aunt's ranch at the age of 15, I observed cattle being handled in a squeeze chute for their vaccination. A squeeze chute is a narrow metal stall that holds the cattle tightly between two metal side panels. Some of the cattle appeared to relax when pressure was applied by the squeeze sides. After I saw this, I tried the squeeze chute and the deep pressure calmed my anxiety. Then I built a squeeze chute-type device that I could get in (Grandin 2006; Grandin and Scariano 1986). It has padded sides that apply pressure on both sides of the body. I got in the squeeze machine on my hands and knees, and the sides applied pressure to the sides of my body. The effect was to have even, deep pressure over a large area of my body. Another feature of the squeeze machine was that I could control the amount of pressure that it applied. This is a really important feature. Even though the pressure was calming, it sometimes becomes overwhelming. When it became too intense, I could release it. At any time, I could stop the pressure.

Sensory Difference

Sensory differences in autism are highly variable. Practical experience and anecdotal evidence both show that some individuals are deep pressure seekers and others are not (Bestbier and Williams 2017). I was a deep pressure seeker. When I was a child, I liked my bed covers tucked in very tight, and I would get under the sofa cushions and ask

my sister to sit on top. The hug machine and other methods for applying deep pressure may have positive effects on some individuals and no effect on others. Further research is definitely needed. Subjects should be chosen to participate in studies depending on whether or not they are a deep pressure seeker. The hug machine and other deep pressure methods are most likely to have a positive effect on individuals who are “deep pressure seekers.”

Research on Deep Pressure

Our first studies on the effects of deep touch pressure assessed the reaction of college students to the hug machine (Grandin 1992). Many students were calmed and relaxed, but a few students felt claustrophobic. It was clear that some people reacted positively and others did not. Edelson et al. (1999) reported that 20 min in the hug machine reduced galvanic skin response in some individuals with autism. Other researches with weighted vests and weighted blankets have reported positive results in some individuals (Fertel-Daly et al. 2001; Mullen et al. 2008). Occupational therapists have found from clinical experiences that deep pressure is most effective if it is applied for 20 min and then taken off. When I used the squeeze machine, I found that the calming effect peaked at 20 min. People working with aggressive dogs have also found that deep pressure over wide areas of the body has a calming effect (Williams and Borchelt 2003). Further studies with dogs showed that a pressure garment reduced heart rate in dogs that were separated from other dogs (King et al. 2014). Studies on sensory-type interventions have been hindered by the vast heterogeneity of individuals with autism. Sensory reactions and sensory oversensitivity are highly variable.

In conclusion, the hug machine or other methods for applying deep pressure may be useful for some individuals and not useful for others. When large numbers of studies are analyzed, the effectiveness of deep pressure is not validated (Losinski et al. 2016). The problem is that deep pressure is only effective for a subgroup of individuals with autism. When all the individuals with an autism label are mixed

together, the pressure responders would be mixed with the pressure non-responders. Deep pressure may be most effective for individuals who actively seek it. Studies are needed that separate the subtypes of sensory problems in autism. The disadvantage of the hug machine is that it is expensive. A smaller sitting design has been developed (Lo and Huang, 2018). Occupational therapists have developed many simpler methods that are easy and economical to use on young children, such as weighted vests, rolling up in gym mats, or laying in tied-together inner tubes (Ayres 1979). The hug machine would be most useful with teenagers and adults because the other methods do not apply sufficient pressure.

Human Figure Drawing Tests

Evon Batey Lee

Pediatrics, Kennedy Center/Vanderbilt University, Nashville, TN, USA

Synonyms

DAP:IQ; Draw-a-person intellectual ability test for children, adolescents, and adults; HFDT

Description

The Draw-A-Person Intellectual Ability Test for Children, Adolescents, and Adults (Reynolds and Hickman 2004) provides one of the most recently standardized scoring systems for calculating an IQ estimate based on human figure drawings. In addition to updated norms, the authors have expanded the age range beyond childhood to include adolescents and adults. The DAP:IQ uses a simple administration procedure and “provides an estimate of cognitive development that is at least an estimate of the lower bound of the person’s ability and does so with a task and scoring criteria that have less cultural specificity than most intelligence tests, verbal or nonverbal” (Examiner’s manual, p. vi).

The DAP:IQ manual states that this test is designed for ages 4 through 89 years and may be administered to individuals or groups. Most individuals complete the drawing in 5 min or less, and

the combination of both administration and scoring is estimated to take 10–12 min. Very few materials are required: the administration/scoring form, the drawing form, two sharpened pencils with erasers, and the Examiner’s manual which includes technical information, normative data, and scoring examples. The DAP:IQ is purported to be appropriate for a wide range of backgrounds and ability levels. While the authors are careful not to say it is “culture-free,” they describe it as “culture-reduced.” However, because it is a drawing task that relies on visual-motor skills, it is obviously not appropriate for individuals with severe motor or visual impairments.

Because the DAP:IQ was devised as a measure of cognitive ability, the authors recommend that examiners have formal training in assessment and knowledge about current theories of cognitive development and neuropsychology. Guidance about the testing environment includes the usual recommendations for freedom from noise and distractions but adds the unique caveat that there should be no large pictures or posters containing human figures in the room that an individual could copy while taking the DAP:IQ.

Task instructions are fairly brief but do require receptive language skills: *I want you to draw a picture of yourself. Be sure to draw your whole body, not just your head, and draw how you look from the front, not from the side. Do not draw a cartoon or stick figure. Draw the very best picture of yourself that you can. Take your time and work carefully. Go ahead* (Examiner’s manual, p. 5).

After the figure is drawn, the examiner assigns points for 23 scoring elements. Scores for each element range from 0 to 3 points. Raw score totals may be converted to a variety of scores: IQ scores ($M = 100$, $SD = 15$), T-scores ($M = 50$; $SD = 10$), z-scores, stanines, percentile ranks, age equivalents, or grade equivalents. The authors used a continuous norming procedure to determine the optimal breakdown of age groupings for the normative tables, with the size of the age groupings ranging from 6-month intervals at 4 through 8 years to 15-year intervals at 75 through 89 years.

The administration/scoring form appears to be well designed and easy to use. The first page

includes space for demographic information, test scores, description of testing conditions, and both individual and group directions. The second and third pages provide written and pictorial guidelines for the scoring criteria for each of the 23 scoring elements.

Historical Background

The DAP:IQ follows a long tradition of using human figure drawings as a means of obtaining information about mental or emotional development. Florence Goodenough (1926) is recognized as the first person to develop a drawing test to measure intelligence in children (Jolley 2010). For her Draw-A-Man Test, children were asked to draw their best picture of a man. This drawing was then scored based on 51 details that pertained to the number of body parts, their proportion, and their attachment to the figure. The points were summed, and the total score was converted to a mental age from which a ratio IQ was calculated (Harris and Pinder 1974). In emphasizing the Draw-A-Man Test's long history, Anastasi (1988) reported that it was "used without change from its original standardization in 1926 until 1963." It was then revised by Dale B. Harris and published as the Goodenough-Harris Drawing Test (1963). The age range was extended to include young adolescents, and three drawings were required rather than just one (i.e., children were asked to draw a picture of a man, a woman, and themselves). Scoring criteria were expanded, and separate norm tables were developed for boys and girls, though the self-drawing was not scored.

A few years after Harris' revision, Koppitz (1968) developed another HFDT based on drawings by nearly 2,000 children between 5 and 12 years of age. Children were only asked to draw one figure, and this was scored according to 30 developmental items derived from the Goodenough-Harris test. Items were grouped by expected, common, not unusual, and exceptional details, and the total score could be converted to an IQ score. In contrast to the previously described HFDTs, Koppitz (1968, 1984) viewed

her drawing test as both a developmental test *and* a projective test.

After another 20 years, Naglieri (1988) published the Draw-a-Person: A Quantitative Scoring System (DAP) which was reported to update and improve the prior scoring systems and expand the norm group. Consistent with the Harris revision, children drew three figures, but the self-drawing was scored, and the three scores were averaged. Rather than having separate norms for boys and girls, Naglieri presented only one conversion table for all three drawings. Consequently, Jolley (2010) characterized the Naglieri DAP as a shorter and simpler alternative to the Goodenough and Goodenough-Harris tests.

When the DAP:IQ appeared in 2004, the manual states that no norming on HFDTs had been done since the late 1980s. Like the original Draw-A-Man Test, examinees are asked to draw only one figure – but this time it is a self-drawing. Reynolds and Hickman (2004) emphasized the conceptual aspects of the drawing to estimate IQ. Their stated goals for the DAP:IQ were to provide updated norms, expand the age range to also include adults, and "reduce the influence of motor skills on the scoring of figure drawings" (Examiner's manual, p. 2).

Psychometric Data

The DAP:IQ was normed on a sample of 3,290 individuals from 46 states. The sample was decreased to 2,295 to closely match the U.S. Bureau of the Census (2001) demographic characteristics in terms of geographic area, gender, race, Hispanic origin, family income, educational attainment of parents, and disability status. A continuous norming procedure was used to develop standard scores for the DAP:IQ. Consequently, the size of the age groupings differs across the life span, and it should be noted that there is wide variability in the number of participants included within the specific age groupings (range: $N = 194$ at age 5 years to $N = 14$ at 75–89 years).

Chapter 5 of the Examiner's manual provides information about the reliability of the DAP:IQ

test scores in terms of content sampling, time sampling, and interscorer reliability. With regard to content sampling, internal consistency reliability of the scoring elements for the entire normative sample was calculated using Cronbach's coefficient alpha. The median alpha reliability was 0.82, with the lowest being 0.74 at age 4. The standard errors of measurement for all 22 age intervals are 4–5 standard score points. Coefficient alphas were also calculated for selected subgroups by gender, racial/ethnic origin, and self-identified handedness, with all of the coefficients falling above 0.73. Evidence for test-retest reliability was based on one small study of 45 individuals ranging from 6 through 57 years of age. They were tested and then retested after a 1-week interval, and the standard scores obtained from the two sessions correlated at 0.84. Interscorer reliability was established by two studies. In the first study, two PRO-ED staff members independently scored 31 drawings completed by individuals 11–75 years of age. In the second study, two PhD graduate students each scored 148 protocols for children from 6 to 11 years. The IQs obtained by these examiners correlated very highly – .95 for the first study and .91 for the second. In an independent study, Williams et al. (2006) supported the reliability results reported in the DAP:IQ manual. They administered the DAP:IQ to a sample of college students aged 19–29 years who were primarily Caucasian and female. Using scores from 110 undergraduate and graduate students to examine internal consistency, they obtained alpha coefficients of 0.82 – which matched the values reported in the DAP:IQ manual. With a smaller subsample of 31 students, the interscorer reliability coefficient was 0.83 which is somewhat lower than the correlation reported in the manual. The intrascorer reliability in this study was 0.92, but this calculation was not reported in the manual, so it is not possible to make a comparison.

Evidence for the validity of the DAP:IQ is provided from several different vantage points in the manual. The authors state that the DAP:IQ is “offered as a measure that estimates overall cognitive ability as represented in the drawing or construction of the human figure” (Examiner's

manual, p. 24). They support the validity of the DAP:IQ by citing historical evidence of the use of human figure drawings by clinicians and researchers for over 100 years. The scoring elements of this current test were generated based on knowledge of the literature “but without reference to any other scoring criteria” (Examiner's manual, p. 25). However, it is unclear how one could be familiar with the previous tests and not be influenced by their scoring systems. After the DAP:IQ scoring criteria were developed, Reynolds and Hickman had them reviewed by PhD-level psychologists, special educators, and measurement specialists affiliated with the PRO-ED research department. Two studies comparing DAP:IQ scores with scores from the Koppitz for children 4–11 years and one study comparing scores with the Goodenough-Harris for children 6–11 years yielded strong correlations of 0.85 to 0.86.

The DAP:IQ was also studied in relation to other frequently administered tests of intelligence, aptitude, and achievement. For example, a correlation of 0.46 was obtained between the DAP:IQ scores and the Full Scale IQ scores from the Wechsler Intelligence Scale for Children – Third Edition (WISC-III) administered to a sample of 211 children between 6 and 11 years. Because the correlation was higher between the DAP:IQ and the performance IQ (0.49) than the verbal IQ (0.33), this was interpreted as supporting the contention that the DAP:IQ is more closely associated with nonverbal as compared to verbal skills. Correlations between the DAP:IQ and other measures (e.g., Detroit Test of Learning Aptitude-Primary: Second Edition, Woodcock Johnson Revised: Tests of Achievement, and Wechsler Individual Achievement Test) were consistent with the WISC-III results in yielding moderate correlations.

Clinical Uses

Despite the time and effort devoted by the authors to design and validate this measure, questions remain about when it is appropriate to administer and for what purpose. The authors

state that the DAP:IQ is designed to “improve the pervasive practice of evaluating human figure drawings as a measure of cognitive ability” (Examiner’s manual, p. v) and further suggest that it is appropriate for large screening efforts, in part because it lacks significant language demands and cultural bias. However, because carefully constructed brief IQ measures that assess a wider array of skills have been developed (e.g., Kaufman Brief Intelligence Test – Second Edition, Reynolds Intellectual Screening Test, and Wechsler Abbreviated Scale of Intelligence) and because the DAP:IQ correlates only moderately with more comprehensive measures of intelligence, aptitude, and achievement, it does not seem advisable to use the DAP:IQ to assess cognitive ability or to make placement decisions. It still may be useful to clinicians who utilize drawings as a means of building rapport or facilitating conversation.

Reading comprehension disorder

Short Description or Definition

“Hyperlexia” is a term used, most often, to describe skilled word reading, that is, decoding print to speech, in the absence of concomitant reading comprehension ability. Hyperlexia is not a formal diagnosis; thus, the term is used inconsistently to describe a heterogeneous group of individuals. These descriptions most often refer to individuals whose reading decoding skills exceed their reading comprehension skills, usually assessed via a discrepancy in standard scores. However, other descriptions include individuals with ASD who exhibit precocious reading ability across both decoding and comprehension. Consequently, hyperlexia can refer to individuals with above average reading comprehension and even further above average reading decoding skills as well as individuals with poor reading decoding skills and even poorer reading comprehension skills, for example, individuals who can successfully read aloud but may have no functional language and profound intellectual disability. There is no “gold standard” for defining hyperlexia. Nevertheless, the common depiction of an individual with hyperlexia is a child with an autism spectrum disorder, who begins reading words at a very early age without explicit instruction and without any apparent comprehension of the text.

Categorization

The current characterization of hyperlexia, and the operational definition most often used, is an

individual with an autism spectrum disorder who exhibits precocious word-reading skills. As these individuals develop, their comprehension skills almost invariably begin to even out with their decoding skills because, once mastered, word decoding does not get harder. Despite this operational characterization, the field does not have a single cohesive model for why hyperlexia emerges. Prior hyperlexia research has focused on characterizing comprehension deficits in these individuals, concluding that, although advanced, their word-decoding skills are no different from those of typically developing readers (Aram 1997) or that these skills simply represent preserved “cognitive modules” specialized for processing words (O’Conner and Hermelin 1994).

Epidemiology

There are very few papers that attempt to characterize the prevalence of hyperlexia. The most recent and thorough estimate comes from a sample of 80 children with developmental delays (Grigorenko et al. 2002). The paper employed a discrepancy criterion wherein children were categorized as hyperlexic if their reading-decoding scores were two or more standard deviations higher than their IQ scores. Using these criteria, 12 of the 80 children were characterized as hyperlexic. However, as this is only one study with a relatively small sample, further research is required to determine if these results are comparable across different age ranges and populations.

Natural History, Prognostic Factors, and Outcomes

The term “hyperlexia” was first used in the late 1960s by Silberberg and Silberberg (Silberberg 1967) to describe children in the classroom who were able to read printed words but failed to adequately comprehend text. This description distinguished between word decoding, the ability to decode a printed word to speech, and reading comprehension, the ability to garner meaning from printed text. It is important to note both features of this description: (1) Hyperlexia was

not characterized as a strength; these children were identified because of their reading comprehension difficulties. (2) The reading difficulties these children exhibited were not associated with decoding the printed word. As the subsequent 40 years of research showed, many children who struggle with reading do so at the word-decoding level, and these difficulties can, and often do, lead to difficulties in reading comprehension, but what was described in the hyperlexia literature was a reading difficulty at the level of comprehension in the presence of otherwise skilled decoding.

Subsequent hyperlexia research, primarily driven by small samples and case studies, described a heterogeneous group of children. Typically, these children have autism spectrum disorders (ASDs), are early readers, and exhibit difficulty with reading comprehension. Characterizations in the literature broadly range from individuals with ASDs who would otherwise not be expected to read due to age, or severe language or cognitive disability, and individuals with ASDs who exhibit a disparity between their ability to decode and comprehend text but would otherwise be expected to be able to learn to read (Graziani et al. 1983; Nation 1999; Sliberberg 1967). Importantly, the published literature is composed of primarily case reports and small samples from fewer than 100 papers in the last four decades; thus, it is difficult to make strong conclusions regarding the characterization of these individuals.

Successful reading relies on the development of spoken language. Because many individuals with ASD exhibit language delays or dysfunction, it would be expected that they would show similar difficulties with reading, and many do. However, some individuals with ASD and hyperlexia successfully read words despite profound language impairments. Printed words are symbols that represent the sounds of spoken words. Thus, reading develops upon the scaffold of spoken language. This dependence on spoken language highlights the inconsistency of precocious word decoding in children with ASDs, as language and communicative impairments are part of the diagnostic criteria of ASD. Furthermore, it is not the case that children without language delays exhibit hyperlexia; quite the contrary, there are children

with profound language impairments who nonetheless begin to read with no apparent instruction. It is unknown what leads to the development of successful reading in the presence of language dysfunction in some individuals with ASD. Hyperlexia in individuals with language impairments is inconsistent with the developmental trajectory of typical reading, and further research is required to elucidate our understanding of the phenomenon. It has been proposed that hyperlexia is the result of a circumscribed interest in letters and words. This explanation is in line with the clinical presentation of circumscribed interests in ASDs and the obsession with words and letters that some individuals with hyperlexia exhibit. Nevertheless, successful word decoding requires mastery of the speech sounds of the language; this mastery requires attention to spoken language. Thus, theories of hyperlexia as the result of a circumscribed interest must reconcile the mastery of speech sounds, a very social domain, with the clinical expression of ASDs, where social information is often avoided or ignored.

Clinical Expression and Pathophysiology

The clinical expression of hyperlexia is one of heterogeneity. However, many standardized measures for reading have allowed insight into the reading mechanism of these children. First and foremost is that these individuals are decoding and not memorizing words. It had been hypothesized that these children have a savant-like memory for words wherein they memorized entire words as pictures and then named them; however, research has shown this not to be the case. Several studies have shown that these individuals are able to successfully read pseudowords, for example, pronounceable but novel words like “loink” or “ugcrity” (Cardoso-Martins and Da Silva 2008; Newman et al. 2007). Furthermore, tests of memory do not show these individuals to perform better than their typically developing peers. Secondly, while these individuals do exhibit comprehension difficulties, these difficulties are in line with what would be predicted by their IQ and oral language skills; thus, it is not that their reading comprehension performance is unexpectedly low,

but rather, their word-decoding skills are unexpectedly high (Nation 1999; Nation et al. 2006; Nation and Norbury 2005; Pennington et al. 1987). Importantly, as these individuals get older, their age adjusted word-decoding standard scores will get lower and lower. This does not reflect a regression; instead, it reflects that word-decoding skills reach a ceiling of difficulty. As individuals get older, their peers are attaining mastery in word decoding.

For both the caretaker and clinician, it is important to appreciate just how scant the hyperlexia literature is, lest they be guided by out of date, underpowered, and unreplicated research. While the quality of research in hyperlexia is high, it is based on a very small group of children. Since the term was coined in 1967, there are fewer than 100 peer-reviewed articles focusing on hyperlexia. Of these articles, there are multiple review papers, case studies, and instances where the same individual is included in the sample of multiple papers. The latter issue is understandable as children are often seen over multiple occasions by the same clinicians or recruited for multiple studies at the same institution. However, it highlights just how little research there is to base clinical practice on. Finally, there are several papers with provocative titles, claiming that hyperlexia is a marker for positive outcomes in ASDs, or how to accurately define and diagnose hyperlexia, when there is very little data to base these claims on.

Evaluation and Differential Diagnosis

Again, as there is no formal diagnosis of hyperlexia, there is no standardized assessment procedure. However, it can be very useful to have a clear characterization of reading skills in children and individuals in academic settings, especially if they are having reading difficulties. In addition to a clinical characterization for autism spectrum disorders including both cognitive and language abilities, a comprehensive assessment of written language proficiency is warranted. This assessment would include, depending on the age and functioning of the individual, measures of reading decoding, single-word reading, reading

comprehension, reading fluency, phonological processing, and concepts of print. The expected profile from this assessment for an individual with hyperlexia would be one of very strong single-word-decoding skills contrasted by relatively poor reading comprehension skills. Given that individuals with ASDs exhibit a range of communicative and cognitive abilities, it is important that the assessments used during evaluation are chosen to provide an accurate estimate of skill; the particular assessments will vary based on the participant's age and cognitive ability, as well as their native language.

Treatment

Treatment recommendations for reading comprehension difficulties in individuals with hyperlexia combine best practices in reading comprehension interventions, for example, oral language training (Clarke et al. 2010; Snowling and Hulme 2011), and awareness of the specific needs of individuals with ASDs, for example, difficulty with inference, figurative language, and executive functioning. Specifically, direct instruction in reading comprehension strategies includes those used before, during, and after reading a text, including activating background knowledge, previewing vocabulary and content, comprehension monitoring (with embedded stimulus cues), and reviewing text. The use of graphic organizers matched to text types, for example, Venn diagram for cause and effect, is often important for organizing information and providing a visual support for language-based tasks. Finally, for many students with ASDs, a focus on the development of nonfiction reading comprehension and written expression will be important, as these are the text types that will constitute the majority of their academic classes moving forward.

Hyperresponsiveness

Winifred Schultz-Krohn

Department of Occupational Therapy, San José State University, San José, CA, USA

Definition

This term, used in the context of sensory processing, refers to the exaggerated responses demonstrated by a person following a sensory experience. The term overresponsiveness is also used in the literature. The nervous system is designed to receive and register incoming sensory information in a graded manner where stronger sensory information is registered at a more intense level. Individuals exhibiting hyperresponsiveness or overresponsiveness demonstrate a heightened state of arousal when seemingly non-noxious or subtle sensory stimuli are presented. An individual may be hyperresponsive to only one form of sensory information such as auditory or tactile or an individual may be hyperresponsive to several types of sensory experiences. An individual with hyperresponsiveness may actively avoid situations that include a specific form of sensory stimulus such as avoiding noisy rooms or an individual may demonstrate unusual behaviors when encountering overwhelming sensory experiences such as grimacing, crying, or becoming agitated as the sensory experience becomes increasingly intense. The hallmark of hyperresponsiveness is an overreaction to a seemingly

subtle or non-noxious sensory experience. Occupational therapy intervention addresses this hyperresponsiveness from several perspectives to allow the individual more opportunities to engage in everyday activities.

Definition

Serotonin [5-hydroxytryptamine (5-HT)] is a neurotransmitter with effects in the central nervous system and some peripheral organs. It plays a key role as a growth factor in the immature mammalian brain, directing proliferation and maturation (Whitaker-Azmitia 1993). As a result, serotonin has long been implicated in the pathophysiology of autistic disorder (autism), with the first report of

elevated whole-blood serotonin (WBS) levels in patients with autism published in 1961 by Schain and Freedman. WBS levels have been a consistent finding in individuals with autism in a number of research studies, although it is unclear what role serotonin exactly plays, if any, in the pathophysiology of autism (McDougle et al. 2003).

The degree of elevated serotonin, referred to as “hyperserotonemia,” has been defined using various cutoffs. One 1987 paper by Anderson et al. compared the WBS levels of 40 children with autism to that of 87 normal children. The 95th percentile of WBS in the normal group was used to define “hyperserotonemia” (WBS greater than 200 ng/ml), and 38% of autistic individuals were found to be hyperserotonemic. The causal reason for this increase is unknown as these subjects did not appear to represent any identifiable subgroup. Other studies have attempted to study WBS or platelet 5-HT levels in children with autism with regard to age, pubertal development, ethnicity, cognitive impairment, or familial WBS or platelet 5-HT levels, with mixed results (McBride et al. 1998; Croonenberghs et al. 2000; Leboyer et al. 1999; Piven et al. 1991). Overall, many but not all investigations have found elevated WBS levels in prepubertal autistic subjects compared to controls, whereas most normal subjects show an age-related decline of WBS (McDougle et al. 2003). Studies that attempt to probe 5-HT function via endocrine challenges in patients with autism have suggested that 5-HT responsivity may be reduced in autistic subjects compared to controls, particularly in adults. These findings have led researchers to propose that an abnormal maturational process in the 5-HT system may contribute to the pathophysiology of autism. Studies of urinary excretion of 5-HIAA, whole-blood tryptophan concentrations, and baseline levels of cerebrospinal fluid (CSF) 5-HIAA have not found significant differences between autistic subjects and controls. Genetic studies of the 5-HT system in autism have also yielded inconsistent results. It is unclear if WBS levels will prove to be a useful measure in the search for genetic susceptibility to autism, but the concept of elevated WBS as a recurring phenomenon in autism continues to intrigue researchers.

Hypo-arousal

Sandra Hodgetts
Pediatrics, University of Alberta, Edmonton, AB,
Canada

Synonyms

[Under-arousal](#)

Definition

Arousal refers to the physiological state of readiness or general state of excitation of one's nervous system. Arousal states lie on a continuum from low to high, and the ability to maintain optimal arousal levels is often required for adaptive interaction with one's environment. Hypo-arousal refers to an arousal state that lies of the low end of this continuum. Behaviorally, hypo-arousal may be observed as under-responsiveness to stimuli and one's environment, for example, as lethargy, inattention, apathy, or boredom.

Theories of hypo-arousal in autism originated in the 1960s, linked directly to the idea of autism-specific deficits in the arousal system per se, specifically implicating the reticular activating system (Rimland 1964). Although general arousal levels have since been found to be normal in persons with autism, there is empirical support for under-arousal in response to specific sensory stimuli in many persons with autism. For example, laboratory data has shown physiological under-responsiveness to auditory, tactile, visual, vestibular, and olfactory stimuli compared to typically developing peers matched on chronological age (Ben-Sasson et al. 2009). However, the evidence base for hypo-arousal and under-responsiveness in autism is limited, due to the paucity and methodological limitations of the available studies (Rogers and Ozonoff 2005). Moreover, results are often inconsistent across studies, possibly reflecting a genuine heterogeneity in patterns of sensory responsivity in individuals with autism.

Hyporesponsiveness

Winifred Schultz-Krohn
Department of Occupational Therapy, San José State University, San José, CA, USA

Definition

Hyporesponsiveness: This term, used in the context of sensory processing, refers to the limited responses demonstrated by a person following a sensory experience. The term underresponsiveness is also used in the literature. The nervous system is designed to receive and register incoming sensory information in a graded manner where stronger sensory information is registered at a more intense level. For individuals who have hyporesponsiveness or underresponsiveness, they may have difficulties detecting novel or pertinent sensory information such as watching a quickly approaching car when attempting to cross a street or controlling the speed of pouring milk from a

carton and spilling the milk by overfilling the cup. Individuals with hyporesponsiveness may appear disinterested in surrounding events due to a limited ability to respond effectively to those events. For individuals with hyporesponsiveness, occupational therapy services are provided to enhance the safety and ability of the individual to engage in everyday activities with better accuracy and efficiency.

Hypothalamic-Pituitary-Adrenal Axis

Dorie Glover
Psychiatry and Biobehavioral Sciences,
University of California at Los Angeles,
Los Angeles, CA, USA

Definition

The hypothalamic-pituitary-adrenal axis (HPAA) is a chemical messenger system that generates and regulates glucocorticoids (GC). Cortisol, the principal GC in humans, is central for the maintenance of homeostasis, including basic body temperature, autonomic stability, sleep/wake cycles, feeding and thirst, as well as the functioning of higher-order systems (e.g., learning and memory). As such, the HPAA facilitates neurobiological response to all significant internal signals and external stimuli from the environment. It does so

through the sequential release of neurosubstances in the brain structures of the hypothalamus, pituitary, and adrenal glands.

Historical Background

Widely examined in animal and human research, the hypothalamic-pituitary-adrenal axis (HPAA) is best known as the regulator of the “fight-flight” response to threat, diverting energy resources needed for protective actions and promoting a subsequent return to homeostasis when the threat is no longer present. Such a system exists in all vertebrates (Lovejoy 2005). Thus, the HPAA has been a central focus of basic animal research on fear conditioning, general effects of environmental stress on the developing brain, “learned helplessness” models of depression, as well as human studies of anxiety and mood disorders more generally (Friedman et al. 1996).

In humans, the perception and interpretation of stimuli occurs within the limbic system, consisting

mainly of the hippocampal formation, amygdala, and entorhinal cortex. When stimuli are identified as potential perturbations to the basic state of equilibrium (i.e., physical or emotional “stressors”), the Sympathetic Adrenomedullary (SAM) system and the HPAA are triggered.

The SAM system responds to threat with *immediate* release of norepinephrine and epinephrine through the sympathetic ganglia of the spinal cord, and the adrenal glands, which sit atop the kidneys.

Release of these catecholamines facilitates processes that increase the heart rate, blood pressure, and blood glucose levels in muscles and vital organs in order to allow the body to carry out defensive actions (Fig. 1).

In contrast, the HPAA responds in a much slower fashion (occurring over several minutes). The hypothalamus releases corticotrophin-releasing hormone (CRH/alternatively “factor” or CRF) to the anterior pituitary. The pituitary response to CRH is to release adrenocorticotrophic hormone (ACTH). In turn, ACTH stimulates

Together, the HPAA and SAM systems are responsible for elevations in catecholamine and cortisol levels in response to acute stress and the HPAA system ensures a return to resting levels through the negative feedback system.

Hypothalamic-Pituitary-Adrenal Axis, Fig. 1 Hypothalamic-Pituitary Adrenal axis

release of cortisol from the adrenal glands. Cortisol feeds back to the hypothalamus to inhibit further release of CRH. Thus, the HPAA represents a “negative feedback” loop by which cortisol release is triggered *and* subsequently inhibited.

Verbal reports and behavioral observations from family, caretakers, and service providers confirm frequent disruptive behaviors in children diagnosed with autism spectrum disorder (ASD). These may include unexplained fear or anxiety, agitation, tantrums, aggression, and resistance to seemingly innocuous directives and situations. Such behaviors are consistent with the HPAA regulated actions of “fight or flight” and are often precipitated by efforts to engage the child in social interactions, elicit communication, or thwart preferred stereotypic movements, activities and routines—all of which can be interpreted as a potential threat to a child with ASD.

However, the HPAA has not been viewed as etiologically relevant to core ASD abnormalities (i.e., social reciprocity, communication and restricted range of behaviors, interests and activities) including (a) repetitive stereotypic behaviors (e.g., hand-flapping and other vestibular movements or lining up objects); (b) reduced or inappropriate affect (including no response to common appetitive and aversive stimuli or a fearful response to certain innocuous sensory stimuli); and (c) preoccupation with a single toy or topic.

The absence of a theoretical model linking the HPAA to ASD may account for the limited number of studies examining HPAA functioning in ASD groups. There is some direct evidence for abnormalities specific to the limbic system which triggers HPAA activation (e.g., the size of the amygdala). There are also a few studies showing abnormal levels (higher *and* lower) of peripheral salivary, urinary or plasma cortisol, and plasma ACTH (Hamza et al. 2010), with greater peak elevations and slow recovery in cortisol reactivity to threat in ASD versus controls (Spratt et al. 2011). The “fractional autism triad” proposed by Happe and Ronald (2008), suggests the three symptom domains used to diagnose ASD may not share the same etiology. Hypothesized

etiologically mechanisms of ASD to date do not account equally well for established knowledge of ASD, including the strong genetic component, male predominance of the disorder, early onset (detectable by the age of two), and frequent overlap with epilepsy and other neurodevelopmental comorbidities. Data indicate none of the symptom domains are primary, universal across all ASD cases, or specific to ASD and not other developmental disorders. With such diversity of symptom patterns, it is perhaps not surprising that HPAA findings in ASD have largely been equivocal.

Current Knowledge

The basic functioning of the HPAA is now known to be considerably more complex than early “fight-flight” models indicated and this complexity may also lead to equivocal findings in ASD. Under normal circumstances, cortisol inhibitory feedback allows for a return to homeostasis after threatening stimuli are no longer present. However, when threat is very intense, frequent, or chronic, the effects of the HPAA on target cells and organs may be prolonged. Cortisol and the catecholamines interact with cell receptors to produce short-term changes in cell processes, as well as changes in gene expression that may have long-lasting consequences for cell function. Over time, these effects can lead to brain changes (structural atrophy, suppressed neurogenesis, and synaptic and dendritic remodeling), and ultimately, poor health outcomes across multiple systems, including cardiovascular, metabolic, and immune systems (McEwen and Gianaros 2011).

Such central neurobiological changes may lead to HPAA dysregulation that is opposite to expected patterns. A counterintuitive *low* level of urinary cortisol was first reported in men diagnosed with Posttraumatic Stress Disorder (PTSD) (Yehuda et al. 1990). PTSD is, by definition, a fear-based psychiatric condition. Diagnostic requirements include (a) exposure to a traumatic event involving perceived threat of death or harm to physical integrity of the self or another person and (b) an acute emotional reaction of fear, helplessness, or horror. Brain

imaging studies confirm distinct neurological areas are activated in PTSD patients who show heightened peripheral SAM system reactivity (e.g., increased heart rate) versus those showing blunted reactivity (Lanius et al. 2010) with an explanatory proposal that there are two forms of PTSD. These and subsequent studies in other psychiatric populations (e.g., Major Depressive Disorder: Ahrens et al. 2008; Panic Disorder: Petrowski et al. 2010) and otherwise healthy individuals experiencing chronic stress (e.g., Juster et al. 2011) demonstrate the bidirectional nature of HPA output at rest and/or in response to new threat. The general direction of HPA dysregulation (hyper- vs. hypo responsive) is thought to depend upon characteristics of the threat (e.g., the intensity, frequency, and chronicity), the timing of assessment relative to the threat (immediate or minutes/hours versus days or months), or to the developmental stage in which the threat occurs (McEwen 2010). Also, the directional impact of cortisol on other neurotransmitters and systems appears to depend upon the perceived anticipatory immediacy of new and recurring threat (Sapolsky et al. 2000). Of note, these are environmental, not genetic factors.

The experiential nature of threat effects on HPA reactivity is demonstrated in a study of monozygotic twins discordant for bullying (one with and one without a victimization history) (Ouellet-Morin et al. 2011). Bullied twins showed a blunted cortisol response to a psychosocial stress test, whereas their non-bullied siblings had a normal cortisol rise. There was no evidence that these group differences were due to genetic makeup, family environment, preexisting or concomitant individual factors, and the perception of stress or the level of subjective emotional responding to the stress test.

Given the heterogeneity of HPA findings among non-ASD populations and the considerable heterogeneity of symptoms in ASD patients specifically, assessment of HPA functioning by currently available measurement methods from peripheral urine, saliva, or blood may not yield clear data. Nonetheless, connections between the hypothalamus and pituitary that are proximal to

and interact with those of the HPA system (see Gardner and Shoback 2007) have been directly implicated in affiliative behavior relevant for ASD.

The hypothalamus is a cone-shaped brain structure that sits below the thalamus, projecting downward into the pituitary (infundibular) stalk which ends at the roundish-shaped pituitary gland (Afifi and Bergman 1998). CRH is secreted in the paraventricular nucleus (PVN) and the arcuate nucleus (AN) of the hypothalamus. CRH is transported to the anterior pituitary via a system of blood vessels called the *hypophyseal portal system*, where it stimulates release of ACTH. The PVN is also the primary originator of oxytocin (OXY) and one of two hypothalamic nucleus sources of arginine vasopressin (AVP) (known alternatively as vasopressin, argipressin, or antidiuretic hormone (ADH)). [The primary source of AVP is thought to be the supra-optic nucleus.] (Fig. 2).

Cell bodies of OXY and AVP neurons have direct distal axon terminals in the posterior pituitary, and as such, are not neurosecreted via blood vessels like CRH and other hormones traveling into the anterior pituitary. Despite this difference, mutual origination from the PVN and excitatory and inhibitory cross-talk between CRH, OXY and AVP suggest these may be more interrelated than previously thought. For example, recent data indicate AVP potentiates CRF stimulation of ACTH and OXY inhibits release of CRF (van den Burg and Neumann 2011). The role of OXY and AVP in affiliative behavior was recently reviewed by Insel (2010). Like CRH, these neuropeptides originate in the hypothalamus and are carried to the pituitary to facilitate further downstream changes. Stimuli perceived as significant may not only elicit agonistic or avoidance behavior (i.e., fight/flight) and thus CRH, but also approach and affiliation behaviors (“tend and befriend”), which are associated with OXY and AVP (Taylor et al. 2000). Building on this concept, Insel reviews evidence for the social effects of oxytocin and vasopressin within and across species, emphasizing complex interactions among, neuromodulators and species-specific behaviors, including mating, pair-bonding (monogamous or promiscuous),

Hypothalamic-Pituitary-Adrenal Axis,

Fig. 2 Relevant Hypothalamic Nuclei

parental involvement (maternal and paternal), and social structure (solitary or interactive). An interaction between oxytocin and dopaminergic neurotransmission has also been proposed to control social behaviors relevant for ASD (Baskerville and Douglas 2010). Dopaminergic (DA) neuron cell bodies, although not exclusive to this region, are found in the PVN and AN. DA cells project to the anterior pituitary via the tubero-infundibular tract. A recent study of the distribution and morphology of catecholamine elements in the hypothalamus showed them to be almost exclusively dopaminergic synapses (Dudas et al. 2010).

As with bidirectional dysregulation of cortisol in HPAA, behavioral effects of OXY and AVP do not appear to be directly related to levels per se. Instead, receptor location and expression patterns are suggested to be more strongly related to downstream effects (Insel 2010). Current clinical research measurement techniques from peripheral sources (e.g., urine, saliva, and blood) clearly limit the study of central mechanisms occurring within the brain. Nonetheless, the profound social and behavioral deficits seen in ASD may arise from abnormalities in these neuroanatomical areas and corresponding neuroendocrine systems.

Future Directions

Pharmacological and behavioral interventions are known to be effective in dampening the negative sequelae of disruptive behavioral symptoms. Yet, these are likely to be secondary to core domains that temporally precede and act as antecedents to HPAA actions. Whereas the HPAA is likely to play a central role in behavioral symptoms in response to perceived threat, the most parsimonious interpretation of evidence to date is that HPAA abnormalities are secondary consequences of ASD etiology arising from abnormalities in proximal or interrelated areas of the brain.

Hypotonia

Wouter Staal
Neuroscience, Radboud University Nijmegen
Medical Centre Karakter, Nijmegen,
The Netherlands

Definition

A state of reduced muscle tension or resistance to movement in a muscle. Hypotonia is not a disorder on its own but a sign or symptom of many different disorders. In infants, hypotonia may be accompanied by delay in motor skills, drooling and speech difficulties, and hyperflexibility of the joints and tendons.

ICD 10 Research Diagnostic Guidelines

Michael B. First
Department of Psychiatry, Columbia University,
New York State Psychiatric Institute, New York,
NY, USA

Definition

The International Classification of Mental and Behavioral Disorders – 10th Edition is used by over 70% of the psychiatrists in the world. Although the DSM-IV and ICD-10 definitions for the majority of disorders included in both classifications are quite similar, they are rarely identical, and for a substantial minority of disorders, there are significant differences.

Unlike the DSM-IV definitions of mental disorder which are meant to be used in all settings (i.e., clinical, research, administrative, educational), there are actually three versions of the ICD-10 mental disorders section. The “official” version, the one approved by the World Health Assembly and primarily used by administrators,

includes brief glossary definitions for each of the mental disorders. The ICD-10 Clinical Descriptions and Diagnostic Guidelines (CDDG), commonly known as the “blue book” (because of the color of its cover), is “intended for general clinical, educational, and service use” (ICD-10 CDDG, p. 1) and provides descriptions of the main clinical features for each disorder, accompanied in most cases by diagnostic guidelines, “indicating the number and balance of symptoms usually required before a confident diagnosis can be made” (CDDG, p. 1). The ICD-10 Diagnostic Criteria for Research (DCR), commonly known as the “green book,” is intended primarily for researchers and contains specific diagnostic criteria based on the definitions in the ICD-10 CDDG. These diagnostic criteria were designed to be “deliberately restrictive: their use allows the selection of groups of individuals whose symptoms and other characteristics resemble each other in clearly stated ways” (DCR, p. 1).

A comparison of the diagnostic guidelines and diagnostic criteria for research for a particular ICD-10 disorder usually reveals much greater precision and specificity in the DCR in terms of required minimum and maximum durations and required numbers of symptom features. For example, Table 1 shows the ICD-10 diagnostic guidelines for childhood autism, and Table 2 shows the corresponding diagnostic criteria for research. Although the diagnostic guidelines, like the diagnostic criteria for research, require qualitative impairments in both reciprocal social interaction

ICD 10 Research Diagnostic Guidelines, Table 1 ICD-10 Diagnostic guidelines for childhood autism (ICD-10 CDDG, pp. 253–254) Reprinted by permission of World Health Organization

Usually there is no prior period of unequivocally normal development but, if there is, abnormalities become apparent before the age of 3 years. There are always quantitative impairments in reciprocal social interaction. These take the form of an inadequate appreciation of socio-emotional cues, as shown by a lack of response to other people's emotions and/or a lack of modulation of behavior according to social contexts; poor use of social signals and a weak integration of social, emotional, and communicative behaviors, and especially, a lack of socio-emotional reciprocity. Similarly, quantitative impairments in communication are universal. These take the form of a lack of social usage of whatever language skills are present; impairment in make-believe and social imitative play; poor synchrony and lack of reciprocity in conversational interchange, poor flexibility in language expression and a relative lack of creativity and fantasy in thought processes; lack of emotional response to other people's verbal and nonverbal overtures; impaired use of variations in cadence or emphasis to reflect communicative modulation; and a similar lack of accompanying gesture to provide emphasis or aid meaning in spoken communication.

The condition is also characterized by restricted, repetitive, and stereotyped patterns of behavior, interests, and activities. These take the form of a tendency to impose rigidity and routine on a wide range of aspects of day to day functioning; this usually applies to novel activities as well as to familiar habits and play patterns. In early childhood particularly, there may be specific attachment to unusual, typically non-soft objects. The children may insist on the performance of particular routines in rituals of a nonfunctional character; there may be stereotyped preoccupations with interests such as dates, routes, or timetables; often, there are motor stereotypies; a specific interest in nonfunctional elements of objects (such as their smell or feel) is common; and there may be a resistance to changes in routine or in details of the personal environment (such as the movement of ornaments or furniture in the family home).

and communication, and by the presence of restricted, repetitive, and stereotyped patterns of behavior, interests, and activities, there is no indication about how many of the exemplary symptoms are required for the diagnosis; this judgment is left up to the clinician. In contrast, the diagnostic criteria for research specify that at least six autistic symptoms must be present, with at least two symptoms indicative of a qualitative abnormality in reciprocal social interaction, at least one

ICD 10 Research Diagnostic Guidelines, Table 2 ICD-10 Diagnostic Criteria for Research for F84.0 childhood autism (ICD-10 DCR, 147–149)

A. Abnormal or impaired development is evident before the age of 3 years in at least one of the following areas:

- (1) Receptive or expressive language as used to social communication
- (2) The development of selective attachments or of reciprocal social interactions
- (3) Functional or symbolic play

B. A total of at least six symptoms from (1), (2), and (3) must be present, with at least two from (1) and at least one from each of (2) and (3):

(1) Qualitative abnormalities in reciprocal social interaction are manifest in at least two of the following areas:

- (a) Failure adequately to use eye-to-eye gaze, facial expression, body posture, and gesture to regulate social interaction
- (b) Failure to develop (in a manner appropriate to mental age and despite ample opportunities) peer relationships that involve a mutual sharing of interests, activities, and emotions
- (c) Lack of socio-emotional reciprocity as shown by an impaired or deviant response to other people's emotions; or lack of modulation of behavior according to social context; or a weak integration of social, emotional, and communicative behaviors
- (d) Lack of spontaneous seeking to share enjoyment, interests, or achievements with other people (e.g., a lack of showing, bringing, or pointing out to other people objects of interest to the individual)

(2) Qualitative abnormalities in communication are manifest in at least one of the following areas:

- (a) A delay in, or total lack of, development of spoken language that is not accompanied by an attempt to compensate through the use of gesture or mime as an alternative mode of communication (often preceded by a lack of communicative babbling)
- (b) Relative failure to initiate or sustain conversational interchange (at whatever level of language skills is present), in which there is reciprocal responsiveness to the communications of the other person
- (c) Stereotyped and repetitive use of language or idiosyncratic use of words or phrases
- (d) Lack of varied spontaneous make-believe or (when young) social imitative play

(3) Restricted, repetitive, and stereotyped patterns of behavior, interests, and activities are manifest in at least one of the following areas:

- (a) An encompassing preoccupation with one or more stereotyped and restricted patterns of interest that are abnormal in content or focus; or one or more interests that are abnormal in their intensity and circumscribed nature though not in their content or focus

(continued)

ICD 10 Research Diagnostic Guidelines, Table 2
(continued)

(b) Apparently compulsive adherence to specific, non-functional routines or rituals
(c) Stereotyped and repetitive motor mannerisms that involve either hand or finger flapping or twisting, or complex whole body movements
(d) Preoccupations with part-objects or non-functional elements of play materials (such as their odor, the feel of the surface, or the noise or vibration that they generate)
C. The clinical picture is not attributable to other varieties of pervasive developmental disorder, specific developmental disorder of receptive language (F80.2) with secondary socio-emotional problems; reactive attachment disorder (F94.1) or disinhibited attachment disorder (F94.2); mental retardation (F70-F492) with some associated emotional or behavioral disorder; schizophrenia (F20.-) of unusually early onset, and Rett's syndrome (F84.2)

symptom indicative of a qualitative abnormality in communication, and at least one symptom indicative of restricted, repetitive, and stereotyped patterns of behavior.

ICD-10 lists six specific disorders within its pervasive developmental disorders section (F84.0 Childhood autism, F84.1 Atypical autism, F84.2 Rett's syndrome, F84.3 Other childhood disintegrative disorder, F84.4 Overactive disorder associated with mental retardation and stereotyped movements, and F84.5 Asperger's syndrome), and one residual disorder (F84.9 Pervasive developmental disorder, unspecified) for cases that do not meet the criteria for any of the specific pervasive developmental disorders included in this section. Pervasive developmental disorders, according to the ICD-10 CDDG, are "characterized by qualitative abnormalities in reciprocal social interactions, and in patterns of communication, and by restricted, stereotyped, repetitive repertoire of interests and activities" (ICD-10, CDDG, p. 252). Because the category overactive disorder associated with mental retardation and stereotyped movements is noted in the ICD-10 to be "an ill-defined disorder with uncertain nosological validity" and because it resembles the other disorders in this section only by virtue of the presence of stereotyped movements,

it will not be discussed any further. Notably, while DSM-IV includes criteria sets for childhood autism (called "autistic disorder" in the DSM-IV), Rett's syndrome (called Rett's disorder), other childhood disintegrative disorder (called "childhood disintegrative disorder"), and Asperger's syndrome (called "Asperger's disorder"), it does not include a category for atypical autism. All cases of pervasive development disorder not meeting criteria for one of the specific disorders are classified as pervasive developmental disorder not otherwise specified, a category that subsumes the ICD-10 categories of atypical autism and pervasive developmental disorder, unspecified.

Childhood autism (Tables 1 and 2) is characterized by abnormalities in all three areas (i.e., social interaction, communication, range of interests) and are evident prior to age 3. Atypical autism differs from childhood autism in terms either of age of onset or of failure to manifest symptoms from all three of the characteristic areas of abnormalities in autism. Three subtypes are provided: F84.10 (atypicality in age of onset) for cases that meet the symptomatic requirements but for which abnormal or impaired development is evident only after the age of 3 years; F84.11 (atypicality in symptomatology) for cases in which abnormal development is evident before age 3 but for which there are abnormalities in social interactions, communication, or repertoire of interests and activities but not all three; and F84.12 (atypicality in both age of onset and symptomatology) for cases that fail both the age of onset and symptom requirements for autism. The remaining specific ICD-10 pervasive developmental disorders have distinguishing features in addition to abnormalities of social interaction, communication, or repertoire of interests and activities and preempt the diagnoses of childhood autism and atypical autism, i.e., if criteria are met for one of these disorders, childhood autism and atypical autism are not also diagnosed even if criteria were to be met for them.

Rett's syndrome (see Table 3), which appears only in girls, has a very characteristic onset, course, and symptomatology. Apparently normal development for the first 5 months is followed by

ICD 10 Research Diagnostic Guidelines, Table 3 ICD-10 Diagnostic Criteria for Research for F84.2 Rett's syndrome (ICD-10 DCR, p. 151)

A. There is an apparently normal prenatal and perinatal period and apparently normal psychomotor development through the first 5 months and normal head circumference at birth

B. There is deceleration of head growth between 5 months and 4 years and loss of acquired purposeful hand skills between 5 and 30 months of age that is associated with concurrent communication dysfunction and impaired social interaction and the appearance of poorly coordinated/unstable gait and/or trunk movements

C. There is severe impairment of expressive and receptive language, together with severe psychomotor retardation

D. There are stereotyped midline hand movements (such as hand wringing or "hand washing") with an onset at or after the time when purposeful hand movements are lost

deceleration of head growth and loss of previously acquired hand skills accompanied by communication dysfunction and impaired social interaction and the appearance of unstable gait and trunk movements and hand stereotypies. Childhood disintegrative disorder (see Table 4) is distinguished by its requirement that the child have evidence of normal development up to the age of at least 2 years followed by the definite loss of previously acquired skills accompanied by qualitatively abnormal social functioning. Asperger's syndrome (see Table 5) is characterized by the same kind of qualitative abnormalities of reciprocal social interaction and restricted stereotyped interests and activities that are typical of autism, but there is no general delay or retardation in language or cognitive development. Although a diagnosis of atypical autism with atypicality in symptomatology would also apply to such cases (i.e., abnormalities in two out of the three areas required in childhood autism), a diagnosis of atypical autism does not also apply because Asperger's syndrome is given precedence.

Historical Background

Among all the disorders in ICD-10 and DSM-IV, the criteria sets for the pervasive developmental

ICD 10 Research Diagnostic Guidelines, Table 4 ICD-10 Diagnostic Criteria for Research for F84.3 other childhood disintegrative disorder (ICD-10 DCR, pp. 151–152)

A. Development is apparently normal up to the age of at least 2 years. The presence of normal age-appropriate skills in communication, social relationships, play, and adaptive behavior at age 2 years or later is required for diagnosis

B. There is a definite loss of previously acquired skills at about the time of onset of the disorder. The diagnosis requires a clinically significant loss of skills (not just a failure to use them in certain situations) in at least two of the following areas:

(1) Expressive or receptive language

(2) Play

(3) Social skills or adaptive behavior

(4) Bowel or bladder control

(5) Motor skills

C. Qualitatively abnormal social functioning is manifest in at least two of the following areas:

(1) Qualitative abnormalities in reciprocal social interaction (of the type defined by autism)

(2) Qualitative abnormalities in communication (of the type defined for autism)

(3) Restricted, repetitive, and stereotyped patterns of behavior, interests, and activities, including motor stereotypies and mannerisms

(4) A general loss of interest in objects and in the environment

D. The disorder is not attributable to the other varieties of pervasive developmental disorder; acquired aphasia with epilepsy (F80.6); elective mutism (F94.0); Rett's syndrome (F84.2); or schizophrenia (F20.-)

disorders, especially the criteria for childhood autism, are the most closely harmonized. This is a direct result of the DSM-IV field trial for autistic disorders which tested various definitions of autism for potential inclusion into DSM-IV. The multisite field trial involved 125 clinicians with varied levels of experience assessing 977 patients (454 with autism, 240 with other pervasive developmental disorders, and 283 with conditions other than pervasive developmental disorders) using a coding system which compared the DSM-III definition, the DSM-III-R definition, the 1990 draft ICD-10 definition, and a proposed DSM-IV definition derived from the results of literature reviews and data reanalyses in terms of agreement with clinician diagnosis (used as a *ersatz* gold standard) and relative to a diagnostic standard

ICD 10 Research Diagnostic Guidelines, Table 5 ICD-10 Diagnostic Criteria for Research for F84.5 Asperger's syndrome (ICD-10 DCR, pp. 153–154)

- A. There is no clinically significant general delay in spoken or receptive language or cognitive development. Diagnosis requires that single words should have developed by 2 years of age or earlier and that communicative phrases be used by 3 years of age or earlier. Self-help skills, adaptive behavior, and curiosity about the environment during the first 3 years should be at a level consistent with normal intellectual development. However, motor milestones may be somewhat delayed and motor clumsiness is usual (although not a necessary diagnostic feature). Isolated special skills, often related to abnormal preoccupation, are common, but are not required for diagnosis
- B. There are quantitative abnormalities in reciprocal social interaction (criteria as for autism)
- C. The individual exhibits an usually intense, circumscribed interest or restricted, repetitive, and stereotyped patterns of behavior, interests, and activities (criteria as for autism; however, it would be less usual for these to include either motor mannerisms or preoccupations with part-objects or non-functional elements of play materials)
- D. The disorder is not attributable to other varieties of pervasive developmental disorder; simple schizophrenia (F20.6); schizotypal disorder (F21); obsessive-compulsive disorder (F42.-); anankastic personality disorder (F60.5); reactive and disinhibited attachment disorders of childhood (F94.1 and F94.2, respectively)

derived through latent class analysis. Based on these analyses, the draft ICD-10 diagnostic criteria had the highest agreement with clinician diagnoses and the best balance of sensitivity and specificity relative to the latent class standard (i.e., sensitivity = 0.87, specificity = 0.98). The ICD-10 diagnostic criteria also had the highest inter-rater reliability ($\kappa = 0.68$) as compared to DSM-III-R ($\kappa = 0.67$) and DSM-III ($\kappa = 0.45$).

Given the superiority of the ICD-10 diagnostic criteria, it was decided that the DSM-IV criteria should be based on these draft ICD-10 criteria. However, because the draft ICD-10 criteria were considered to be more detailed in terms of number of criteria than was desirable for DSM-IV, criteria were identified for elimination based on reliability and signal detection, resulting in the deletion of four criteria and a revision of the scoring algorithm. Because the ICD-10 criteria also were more

detailed and lengthy than desired for DSM-IV, a series of additional analyses were undertaken, resulting in briefer versions of some of the ICD-10 criteria.

Current Knowledge

In terms of number of items and scoring rules (i.e., requiring 6 items total, at least two from the social interaction group and at least one each from the communication group and restricted interests group), the final ICD-10 and DSM-IV criteria are identical. They differ primarily in the complexity of the wording of some of the items. For example, ICD-10 criterion BI3(c) requires “stereotyped and repetitive motor mannerisms that involve either hand or finger flapping or twisting, or complex whole body movements,” whereas the corresponding DSM-IV item requires simply “stereotyped and repetitive motor mannerisms” and provides as examples “hand or finger flapping or twisting or complex whole body movements.” While these two items may superficially appear to be identical, in actuality, the ICD-10 item is more narrow in that it restricts the types of stereotyped and repetitive motor mannerisms to hand and finger flapping or twisting or complex whole-body movements, whereas DSM-IV allows the clinician to count other stereotyped body movements as well. Comparing the final ICD-10 and DSM-IV criteria sets in a group of 123 subjects randomly selected from 16 of the original field trial sites, diagnostic agreement was excellent ($\kappa = 0.86$), suggesting the research studies using either the DSM-IV or ICD-10 criteria would likely yield the same results.

Iceland and Autism

Ingólfur Einarsson

The State Diagnostic and Counseling Center,
Kópavogur, Iceland

Historical Background

When autism was first recognized, when program became available, important historical figures and centers for autism research and service.

Iceland is a rather small island in the North Atlantic Ocean; total size is 103,000 km². Settlers, mainly from Norway, began to arrive in the ninth century (AD). Iceland got independent in 1944 and established a parliamentary democracy (63-members) with a directly elected president as head of state (Iceland 2018). The population grew slowly until the twentieth century (total of 78,000 in the year 1900) but has increased faster in the last 100 years and is at present around 340,000 inhabitants (Hagstofa Íslands 2017). The language spoken is called Icelandic and has its origin in the Old Norse (Iceland 2018). The term “*einhverfa*” is used in Icelandic for the diagnostic term “autism.” This term has been seen in the Icelandic sagas but was first seen related to a psychiatric term in 1939 (Sæmundsen and Guðmundsdóttir 2014). Special educational and intervention services started for a group of children with disabilities in Iceland in the 1970s, along with the development of deinstitutionalization (Bjarnason et al. 2016). A child psychiatric department was first established in 1970, at the National Hospital in Iceland, and around this time professionals were becoming more aware of autism diagnosis. A report of the first child recognized to be diagnosed with autism in Iceland was in 1968. Then there were two girls (2 and 10 years old) diagnosed in 1973 (Sæmundsen and Guðmundsdóttir 2014). At the child psychiatric unit, there were 57 children diagnosed with autism during 1970–1991. The educational services improved for children with disabilities following change in compulsory school act in 1974

and with the development of special educational departments within mainstream schools and with a development of special schools. The State Diagnostic and Counselling Center (SDCC) run by the state (Ministry of Social Affairs) was established in 1986 and in 1997; the center was appointed by the ministry to establish a specialized service around the assessment and intervention for children with autism (Sæmundsen and Guðmundsdóttir 2014). All children and adolescents in Iceland with suspicion of autism were referred to SDCC during the period of more than 10 years. A systematic approach was developed to train professionals to use assessment and diagnostic tools, including ADI-R and ADOS. The methods of early intervention were explored. Two main methods have developed in Iceland, TEACCH and behavioral intervention, based on applied behavior analysis (ABA) (Hjartardóttir and Sigurjónsdóttir 2014). For the last decade due to increased awareness, autism spectrum disorders are diagnosed by other centers in the country as well. The State Diagnostic and Counselling Center still plays a major role to give support and education to parents and professionals working in the area of autism.

Legal Issues, Mandates for Service

Issues related to legal recognition of autism, issues relative to eligibility for support, etc.

Primary health care is generally provided by the state in Iceland. Each region's health-care center provides developmental surveillance until 6 years of age. If there are concerns of developmental growth or symptoms of autism for a child, it might be found during a routine visit or the child might come for extra visits. At each visit the child sees a nurse (n) and for certain visits a doctor (d) as well. The nurse or a midwife meets the child few times and as needed during the post-neonatal period. The first visit at the health-care center is at 6 weeks (n+d). After this scheduled visits are at 9 weeks, (n) 3 (n+d), 5 (n), 6 (n), 8 (n), 10 (n+d), 12 (n), 18 (n+d), 30 (n), and 48 months (n). Parents are often the first to bring up the

worries for their child, so *Parent's Evaluation of Developmental Status* (PEDS) is applied for all children at 18, 30, and 48 months (Directorate of Health 2017a). The *BRIGANCE screen* is applied for all children at 30 and 48 months (Directorate of Health 2017b). In addition large proportion of children in Iceland start play school at a very young age, above 90% of children at 2 years of age (Þorbergsdóttir 2017). Often concerns for the child's developments are brought up by the day care staff. The majorities of play schools are run by the local authorities around the country. Specialist services and support structures should be organized by the local authorities according to special legislations (playschool act, 2008 & regulation 2010). Further assessments are done when the parents agree to do so. The referral for further assessment is usually to the special services provided by the municipality. The local authorities usually have access to clinical psychologists, special educational professional/interventionist, and sometimes a speech and language pathologist or occupational therapist within their team. The team has some resources to do preliminary developmental assessments and screening for autism spectrum symptoms. If the child then needs further diagnostic evaluation, then a referral to a tertiary center, the State Diagnostic and Counseling Center, is made. All referrals are accepted if the child is under 6 years of age with strong suspicion of autism or global developmental delay. All referrals are also accepted for children with significantly limited participation due to autism and/or intellectual disability above 6 years of age (6–18 years). Services for adults with autism might be more fragile. There are teams within the psychiatric units (outpatients) and some private professionals that are providing somewhat limited accessible services.

The directorate of health provides the health-care professionals with some guidelines within the autism. All coding within the health-care system is done with ICD-10 (*International Statistical Classification of Diseases and Health Related Problems, 10th revision*) published by WHO, and the classification of autistic diagnoses is done according to ICD-10 in Iceland (Directorate of Health 2017c). Any child

diagnosed with autism spectrum disorder is able to be supported within the disability services in Iceland (Act on the Affairs of Disabled People 1992).

Overview of Current Treatments and Centers

“Snapshot” of currently prominent and active programs of intervention; its treatment and diagnosis

When the child is diagnosed, the local authorities are obligated to give proper educational services within the mainstream schools (i.e., play schools, compulsory schools). If the child is young and starting play school, parents are encouraged to get involved in choosing the method of early intervention used for their child. As mentioned above ABA and TEACCH are the most prominent methods available in Iceland and used widely at play school level. Almost all municipalities have some experience or trained personal to provide appropriate intervention for the child, but due to increase in ASD diagnoses in recent years, it has become more difficult to meet all diagnosed children with proper quantity of good quality intervention in some areas. The main reason is lack of number of appropriately educated and trained staff at many of the play schools. When the child is at compulsory school age (6–16 years of age), then these specific methods tend not to be the main focus of intervention. The compulsory school intervention is more curriculum educationally driven (special educational needs), rather than able, social, or participation driven. There are no specific centralized intervention centers in Iceland regarding autism specifically. Higher education is widely available (Iceland 2018) in the country and is run directly by the state (Ministry of Education).

Overview of Research Directions

Most significant research programs

Most activities in autism research in Iceland have been done by the State Diagnostic and Counselling Center. Saemundsen's studies have

shown the increasing prevalence in the diagnosis of autism in Iceland in the last decades (Saemundsen et al. 2013). For example, the prevalence of autism in a 1974–1983 birth cohort was 3.8 per 10,000, while it was 8.6 per 10,000 for a younger birth cohort (1984–1993) (Magnússon and Saemundsen 2001). In a study published in 2013, the prevalence of childhood autism was 33.7 per 10,000 (120 per 10,000 for the whole spectrum) in an Icelandic 1994–1998 birth cohort, by the end of 2009 (Saemundsen et al. 2013). From a phenotypic descriptions and genetic analysis, there have been some publications from Icelandic data, some copy number variations (CNV), and some genetic mutations in relation to autism, schizophrenia, and other neurodevelopmental problems (Weiss et al. 2008; Autism Spectrum Disorders Working Group of The Psychiatric Genomics Consortium 2017). There have also been some research activities in cooperation with the University of Iceland, including that children with high-functioning autism rate their quality of life themselves better than their parents (Egilson et al. 2016).

Overview of Training

Ongoing training of providers (teachers, health-care professionals, and others)

The State Diagnostic and Counseling Center provides courses about autism and interventions, for professionals working in the field and for parents (SDCC website 2018).

Social Policy and Current Controversies

Attitudes or social movements with regard to autistic people; debates about autism

The diagnostic practices have been under some focus for few years. Due to increased awareness and observation of the importance of early intervention, there has been improvement in services in general. Many think that there might be some over diagnosis in the field of the autism spectrum disorder. Some think that a driving force is labelling to gain further access to services. This

labelling is also driven by how the funding system is built for the municipalities providing the services. Funding is distributed according to the diagnosis of a child, and the more severe the diagnosis is some more money is provided by a special fund (Jöfnunarsjóður). A recent research exploring this issue has suggested to reduce the emphasis on diagnostic pressure (labelling) and increase early inclusive intervention within the schools in Iceland (European Agency for Special Needs and Inclusive Education 2017).

icons has been evaluated relative to transparency and translucency. Transparency refers to how well an icon's referent can be guessed by an unfamiliar user. Translucency refers to the semantic, linguistic, or conceptual relation of icon and its referent. For example, a photo of an object is highly iconic because it is easily recognized and has a strong visual relation with its referent. An abstract line drawing is less iconic because it is less easily recognized by an unfamiliar user and has a more abstract relation with its referent. There is some evidence that icons may be most easily learned when the icon strongly resembles its referent; this is referred to as the iconicity hypothesis. There is evidence that use of icons can be an effective communication strategy for individuals with autism.

Iconic Systems

Elizabeth Spencer

College of Education and Human Ecology, The Ohio State University, Columbus, OH, USA

Definition

Iconic systems are systems of communication in which icons or symbols are used to represent words or linguistic concepts. Iconic systems are a type of augmentative communication. Iconic systems can be part of a picture exchange system (e.g., PECS) or used in augmentative communication devices. Iconic systems are hypothesized to facilitate communication by a recognition process (e.g., the user recognizes the icon as a picture of the object). In contrast, linguistic systems such as verbal speech involve a recall process (e.g., the user must recall the word that represents that object). Use of iconic systems can be an effective communication strategy for individuals with autism. The concrete and static nature of icons (e.g., a visual symbol has a specific, unchanging referent) and iconic systems (e.g., the system has a set of specific, unchanging rules) may be a reason that iconic systems are effective for individuals with autism. There is evidence that iconic systems can be useful for reducing challenging behaviors in individuals with autism particularly when implemented as part of a communication choice system.

Definition

Idiosyncratic language occurs when the child uses standard words or phrases in an unusual, but meaningful way (Volden and Lord 1991). It is a broad term that can refer to a number of speech characteristics that are errors in the pragmatics of communication. A common characteristic of speech in children with Autism Spectrum Disorder (ASD), idiosyncratic language is described as stereotypical and inappropriate word use. These unusual utterances include pedantic speech, in which the child uses overly specific details.

IEP Matrix: Manuscript

Solandy Forte
The Center for Children with Special Needs,
Glastonbury, CT, USA
Milestones Behavioral Services, Inc., Milford,
CT, USA

An Individualized Education Program (IEP) provides the school team with clear and concise goals and objectives to be targeted across an individual student’s school day and week. It is important for all educators (including service providers) to clearly outline, for implementers of educational and behavioral instruction, the setting(s) in which teaching opportunities need to occur based on the student’s IEP. An IEP matrix can assist the school team (including parents and caregivers) in identifying the settings where specific goals and objectives across all educational domains will be targeted for instruction in a manner that is effective and efficient in order to promote learning and generalization of skills of new and/or acquired skills. Providing the implementers of instruction with an IEP matrix will assist in expediting instruction across settings that is informed and systematic. Further, it will assist the school team in identifying any staff training needs that are specific to executing instruction within a particular setting. This may include educators engaging

in the development and careful review of teaching protocols and lesson plans with implementer that is also paired with modeling and the delivery of feedback. In order for an IEP matrix to be effective, the school team must provide sufficient and adequate staff training to ensure that instruction is being implemented with fidelity.

An IEP matrix is often a document that outlines for the implementer(s) where and when a skill will be targeted for instruction. It will specifically identify times of the day, setting, teaching format, activities, and materials necessary for ensuring that instruction occurs in a systematic fashion to promote generalization of skills day long. This may also serve as a reminder to school team members for when and where instruction needs to occur in order to ensure that teaching opportunities are happening in these settings. The content within the IEP matrix will vary depending on the identified direct instruction (e.g., individual or small group instruction) and inclusion time (i.e., time with non-disabled peers) as well as the student's grade level. The matrix is individualized to meet the unique needs of the student with respect to the setting(s) where instruction will be delivered. Therefore, it may include information relative to the student's accommodations, instructional and prompting strategies, and data collection procedures. It is critical that instruction continues to occur across a variety of settings that are outside of the one-on-one setting particularly after the student has acquired a new skill. An IEP matrix is a useful tool for educators to use when programming for generalization of skills as it will help to identify any resources or supports necessary for successful instruction across the school day.

For a parent or caregiver, the IEP matrix provides a visual representation of where a student is receiving instruction specific to their individualized goals and objectives and also identifies the teaching methods used within each of the settings. It may also identify the implementers (e.g., related service providers, special education teacher, general education teacher, and direct-care staff) of instruction for each of the time intervals across the school day and week. The IEP matrix is intended to guide the school team in delivering instruction across settings and should be modified

or adjusted as necessary to include special school activities, changes in implementers of the IEP, and any new instructional strategies identified to be effective. Further, the IEP matrix is intended to help promote learning of skills not restrict learning to certain settings or situations. It is a working document that allows for modifications as the student continues to progress in all areas of their educational program.

ILAUGH Model

Danielle Geno Kent

The College of Arts and Sciences, The University of Vermont, Burlington, VT, USA

Definition

The ILAUGH model is the training component of the “social thinking” intervention framework designed by Michelle Garcia Winner (2000). It is defined as the multiple skills and concepts an individual must process to have successful social interactions and engage in effective social problem solving. The ILAUGH model was created by Winner to explain to parents and professionals the many components of social thinking or what constitutes good problem solving. In addition, the framework was developed to provide an overall model of social-cognitive deficits. The key concepts of the ILAUGH model include:

Initiation of communication
 Listening with your eyes and brain
 Abstract and Inferential Language/Communication
 Understanding perspective
 Gestalt Processing/Getting the big picture
 Humor and human relatedness

The model was specifically designed as an assessment and intervention approach to address the complex social deficits children with high-functioning autism, Asperger syndrome, and non-verbal learning disabilities struggle with during their day-to-day social interactions.

Historical Background

The ILAUGH model is part of Michelle Garcia Winner's social thinking curriculum, and it investigates traits that have been identified as areas of challenge in persons with social-relatedness disorders. Winner (2000) formulated the ILAUGH model as a result of her work in a school while assessing students' needs for social skills and specific aspects of their curriculum. From there, research was used to support the development of the six key concepts noted in the definition. Originally, the ILAUGH model was created to help students address their social communication needs in academic settings. The ILAUGH model provides an understanding of the relationship between problem solving, social interactions, and the ability to respond to specific areas of the academic curriculum (Winner and Crooke 2009). The ILAUGH model also came about as it was realized that a majority of students on the autism spectrum were weak listeners, failed to use eye contact or sustain conversations, and were challenged to understand the perspectives of another (Dunn Buron and Wolfberg 2008). Most recently, the ILAUGH model has been linked to the social thinking-social learning tree (Winner 2012) and serves primarily as the "trunk" of the tree, with the roots of the tree grounded in biological underpinnings of social thinking (joint attention, executive function, central coherence, theory of mind, emotional regulation and reciprocity) and the branches of the tree representing skills that emerge from the

"trunk's" development (reading comprehension, playing with peers, written expression, conversational skills, working in a group). The leaves of the tree's design are the strategies required to complete the branch, in the case of reading comprehension some skills needed are to summarize what one has read and to organize characters and events (Winner 2012). Currently, it is being developed as a research methodology, and a treatment efficacy study has been recently initiated. The ILAUGH model continues to evolve as an understanding of social cognition research expands.

Rationale or Underlying Theory

The key concepts of the ILAUGH model are grounded in research in the area of social relatedness. A summary of each concept and associated research is described below.

- I – Initiation of Communication* (Krantz and McClannahan 1993). Children with ASD have significant challenges in initiating conversations in stressful situations or when information is not easily understood. Even individuals on the autism spectrum with higher cognitive and linguistic abilities have difficulty with communication, in sharp contrast to the interest they display when talking about a favorite topic of interest.
- L – Listening with Your Eyes and Brain* (Jones and Carr 2004; Kuncie and Mesibov 1998; Mundy and Crowson 1997). Many individuals with ASD struggle with auditory comprehension. From a social perspective, however, listening requires much more than our ears; it includes listening with our eyes, which requires a mastery of joint attention. Once children begin to learn that we listen with our eyes, they can be shown the value of nonverbal cues. This can then expand into teaching children to listen with their whole body.
- A – Abstract and Inferential Language/Communication* (Minshew et al. 1992). Most of our communication is not intended for literal comprehension and, instead, is littered with metaphors and idioms – an area of particular

challenge for individuals with ASD. Accurate message interpretation requires an understanding of literal and figurative language.

U – Understanding Perspectives (Baron-Cohen et al. 1997b; Flavell 2004). To understand the perspectives of others, children must have a developed theory of mind (ToM). Whereas typically developing children acquire ToM between the ages of 4 and 6, children with ASD are often delayed in this acquisition, not fully developing ToM until the age of 10. Perspective taking or ToM considers the following abilities: actively considering and adjusting to the thoughts and emotions of one's self as well as the person(s) with whom one is communicating; actively considering and then comparing and contrasting beliefs (e.g., religious, political, and cultural) of one's self as well as the person(s) with whom one is communicating; actively considering and then adjusting one's message given the prior knowledge or experiences of one's communicative partner (s); and actively considering and then adjusting given the motives and intentions of one's self and/or their communicative partner. Winner (2004a) argues that there is a range of perspective taking skills across the autism spectrum.

G – Gestalt Processing/Getting the Bigger Picture (Fullerton et al. 1996; Shah and Frith 1993). Information is conveyed through conceptual processing, not just factual processing. When engaged in a discussion, conversationalists are constantly assessing the root of the conversation instead of assessing each piece as a separate entity. Conceptual processing is a key component in the understanding of academic and social information. Children who have difficulties with conceptual processing often have difficulties with organizational skills, written expression, and time management while being tangential in their expressive skills.

H – Humor and Human Relatedness (Greenspan and Wieder 2003; Gutstein 2001; Prizant et al. 2006a, b). Although many children on the spectrum have a good sense of humor, they struggle with anxiety secondary to missing

social cues that allow them to understand how to have successful interactions with others. Some children on the spectrum have inappropriate humor, and this must also be addressed during intervention. To support human relatedness, it is important to teach students how to relate to their own emotions as well as that of others while helping them understand and experience the happiness or joy in mutual sharing.

Winner (2002) created the following table to establish the rationale behind the ILAUGH framework and how social-cognitive deficits impact social interaction and classroom functioning.

Key concept	How it affects social interactions	How it affects classroom performance
I – poor initiation of communication or action	Student does not initiate appropriate social interactions	Student does not ask for help Student sits and does nothing when others are doing something In class group work, student may not participate or only knows how to direct others; weak negotiator
L – listening with eyes and brain	Student does not observe other's social cues	Student does not observe other's social cues in the classroom
	Student does not process the meaning of their message	Student does not process the meaning of the message in the academic environment
A – abstract and inferential	Student doesn't infer meaning from social cues and has difficulty deciphering meaning from spoken language	Student is limited in the ability to infer meaning from books and teacher's lectures Student literally interprets all materials

(continued)

Key concept	How it affects social interactions	How it affects classroom performance
U – understanding perspective	Student has difficulty recognizing and incorporating other person’s perspectives into self-regulation in social relationships	Student has difficulty understanding the perspective of characters in literature
		Student has difficulty regulating classroom behavior in consideration of others’ needs
G – gestalt processing; getting the big picture	Student has tangential language	Student attends to details but misses the underlying concept of assignments
	Student fails to track the underlying concept of a verbal interaction	Writing can be tangential; the point is often missed
		Student has difficulty staying with the concept of group work and cooperative learning
H – humor	Student usually has a great sense of humor, but may miss the subtleties of humor	Student responds well to a teacher who has a more relaxed, humorous style, but is still able to follow a fairly structured routine
	Student may not understand if they are being laughed at or laughed with	Student may use inappropriate humor in the class as an attempt to engage others

Goals and Objectives

The ILAUGH model is designed to help professionals/families make sense of the challenges that

are seen by those students with social-learning challenges and also to provide direction for professionals to build on a child’s strengths and needs in intervention. For children with social-relatedness disorders, goals include concepts that are within the realm of social cognition and apply directly to each of the key components of the ILAUGH model. The ILAUGH model was designed to explain ways to succeed at social interaction and engage in successful problem solving. A primary goal of the ILAUGH model is to teach children specific language-based concepts that can be used to explain social expectations and related social emotions and thoughts (Winner and Crooke 2009).

Treatment Participants

Participants should be those with social thinking challenges, including individuals with and without diagnostic labels, primarily those with autism spectrum disorders. In practice, Winner implements the model for children and adolescents with high-functioning autism, Asperger syndrome and those with nonverbal learning disabilities.

Treatment Procedures

The ILAUGH framework offers different components to use in the assessment of a child suspected of having deficits in social cognition. Winner (2002)suggests that there are different ways to assess a child using the ILAUGH framework: (a) observe the student with their peers, across different aspects of their environment, (b) relate with the student without facilitating their social success, (c) use informal assessment tools, (d) administer carefully considered standardized measures, and (e) interview teachers and parents about a student’s daily functioning.

As the ILAUGH model is part of Winner’s social cognition program, there are steps that interventionists take during the process. They must focus on making abstract things concrete,

provide a scaffold for language support, foster self-esteem and self-awareness, program in a progressive manner, and provide structured opportunities for generalization along with ongoing practice (Krasney et al. 2003; Winner and Crooke 2009). To address the components in the ILAUGH model, Winner (2000, 2002, 2005, 2007, 2008) recognized the need to create concrete means of teaching abstract social concepts, so she developed language-based concepts titled *social thinking vocabulary* (Winner and Crooke 2009). Social thinking vocabulary includes terms such as “thinking with your eyes,” expected/unexpected behavior, smart guess/wacky guess, and social fake (Winner and Crooke 2009). Other topics included during social cognition intervention include addressing what good social skills are and recognizing that social rules change with age (Winner and Crooke 2009).

Efficacy Information

There is no research currently available on the efficacy of ILAUGH as a treatment, and/or factors affecting treatment. However, there is research to support the efficacy of the conceptual frameworks used to develop the ILAUGH model (as described above). The skills that children develop to support their social skills interactions are the same skills that are needed for a child to work successfully as part of a group in the classroom (Winner 2002). Social skills deficits have been correlated with academic performance deficits, and thus, by improving social skills, academic skills can also improve (Winner 2004b). Strahan (2003) found that among other things, social skills were a significant predictor of GPA among college-level students.

Crooke, Hendrix, and Rachman (2008) examined the effectiveness of teaching social thinking concepts to students with Asperger syndrome and high-functioning autism (HFA). They found that teaching social concepts resulted in a decrease of unexpected nonverbal/verbal social behaviors.

Outcome Measurement

Currently there are no identified outcome measurement tools.

Qualifications of Treatment Providers

There are no suggested criteria for treatment providers; however, Winner states that assessments of individuals with ASD should be conducted by qualified treatment providers who can evaluate a child’s social, communicative, academic, and play needs.

Imagination

Maria Fusaro and Sally J. Rogers
Department of Psychiatry and Behavioral
Sciences, UC Davis M.I.N.D. Institute,
Sacramento, CA, USA

Synonyms

[Creativity](#); [Generativity](#); [Pretense](#)

Definition

The process of mentally representing concepts that are not immediately, perceptually evident. These concepts include those in the realm of fantasy as well as those in the realm of the non-present reality (e.g., the recent past and the historical past). Imagination skills are evident in symbolic play, perspective taking, problem solving, and other behaviors that require the flexible manipulation of mental representations (see Harris 2000).

In ASD research, imagination in the context of pretend play has received significant attention. Deficits in imaginative play have been useful as a diagnostic marker for ASD, although the interpretation of these deficits has been controversial. One prominent theoretical view holds that the lack of imaginative play indicates a symbolic deficit. From a Piagetian framework, pretend play requires operating from mental representations of previous experiences (Piaget 1962). Leslie (1987) argued that pretense requires the ability to simultaneously hold two representations in mind: the primary (veridical) representation and the imagined representation. This symbolic ability was proposed to be lacking in ASD. This perspective has been challenged by a robust finding of an autism-specific deficit only in the spontaneous generation of pretend play, not in the generation of pretend play in response to elicitation (Lewis and Boucher 1988, 1995). Children with autism generate fewer ideas for pretend acts, with and without props, than controls (Jarrold et al. 1996). However, they are no different from well-matched peers when prompted verbally to perform a pretend act, such as an object substitution, by an adult (Lewis and Boucher 1988). Further, they appear to understand the imagined consequences of an adult's novel, pretend actions (Kavanaugh and Harris 1994). Taken together, children with autism appear able to form and manipulate symbols when suggested by another person but demonstrate a production problem when left to generate pretend acts on their own. An interpretation of these findings is that the pretend play deficit reflects a performance deficit stemming from an autism-specific impairment in generating ideas for play (Jarrold 1997; Jarrold et al. 1996; Lewis and Boucher 1995).

Impairments in generativity may reflect an executive functioning problem that extends beyond the play context, to explain, for example, impairments generating word lists and original ideas for drawings (Lewis and Boucher 1991, 1995). Craig and Baron-Cohen (1999) report diminished performance among school-age children with autism, relative to controls, on relevant tasks that involve generating multiple drawings

from a standard baseline of parallel lines and squiggles, as well as generating ideas for improving a toy, and uses for novel 3-D objects. Additional studies are needed to further understand the interplay of social and cognitive factors underlying diminished imaginative behaviors in autism, in spontaneous pretend play, and in other contexts.

Indications

Imipramine is a tricyclic antidepressant. The term tricyclic refers to the three-ring structure of this class of antidepressant medications. These medications are not used as commonly as in the past as they have been largely replaced by the SSRIs. Imipramine has been used to treat both depression and anxiety.

Mechanisms of Action

While desipramine has highly selective norepinephrine reuptake inhibitor properties, and clomipramine is well known for its more selective serotonin reuptake inhibiting properties, imipramine is intermediate with both norepinephrine and serotonin reuptake inhibiting properties.

Clinical Use (Including Side Effects)

The tricyclic antidepressants have several adverse effects in common including dry mouth, urinary retention, constipation, nausea, increased heart rate, dizziness, and, at higher doses, confusion. The tricyclic antidepressants

also carry some risk of altering the electrical conduction in the heart. They are well known to be fatal on overdose due to their potential for causing cardiac arrhythmia. Because of their known toxicity at higher doses, treatment with tricyclic antidepressants requires blood-level monitoring and electrocardiogram monitoring as well. Finally, the tricyclic antidepressants are also vulnerable to drug-drug interaction. For example, some medications such as SSRIs or certain antibiotics may interfere with the breakdown of tricyclic antidepressant medications. The interference of metabolism of the tricyclic can cause a sharp increase in the blood levels of the tricyclic antidepressants and increase the vulnerability to toxic effects. The tricyclic medications have not been well studied in children or adults with autism.

Imitation

Kathy Lawton

Special Education and Nisonger Center, The Ohio State University, Columbus, OH, USA

Definition

Imitation is considered to be an integral component of young children's social development. The ability to imitate helps lay the foundation for quality social interactions. Empirical findings exploring early imitative abilities in children have found them to relate to an array of

early childhood skills including: social engagement, nonverbal communication, language development, social understanding, and cognitive skills (Young et al. 2011; Rose et al. 2009; Olineck and Poulin-Dubois 2009; Strid et al. 2006).

Historical Background

Although empirical evidence supports the notion that individuals with ASD, as a group, imitate others with less accuracy and less frequency than their typically developing peers (Vivanti and Hamilton 2014), studies reporting on imitation abilities in individuals with ASD report heterogeneity across individuals (Rogers and Dawson 2010; Salowitz et al. 2012; Vanvuchelen et al. 2011; Vivanti et al. 2011). These differences in imitation abilities seem to be related to differences in social and communicative abilities in this population (Young et al. 2011).

A number of studies have provided evidence suggesting a relationship between imitation and language in children with ASD (Ingersoll and Meyer 2011; McDuffie et al. 2007; Toth et al. 2007). In addition, a relationship also appears to exist between imitation and joint attention (Ingersoll and Schreibman 2006; Rogers et al. 2003), play (Vivanti et al. 2013), social reciprocity (McDuffie et al. 2007; Young et al. 2011), and severity of autism symptomatology (Ingersoll and Meyer 2011; Rogers et al. 2003).

While some studies suggest that imitation is a core deficit of autism spectrum disorder (Rogers and Pennington 1991; Rogers 1999), others contend that there is incomplete evidence to suggest that impairments in imitation are unique and specific to ASD (Williams 2008). As such, although there is empirical evidence to support that children with ASD exhibit deficits in their imitation capabilities, there is not a consensus in the field regarding this matter (e.g., Toth et al. 2006). Regardless of whether or not imitation is a core deficit of autism spectrum disorder, its relationship to other critical early childhood skills distinguish it as a worthy target of early intervention.

Current Knowledge

Intervening on Imitation

Due to its prominent role in the development of social and communication skill, there has been much work done on the development of interventions aimed at improving imitation skills in children with ASD. These interventions report promising findings suggesting improvements in object imitation (Ingersoll and Gergans 2007; Ingersoll and Schreibman 2006), motor imitation (Ingersoll et al. 2006), gesture imitation (Ingersoll et al. 2007), and overall imitation (Ozonoff and Cathcart 1998; Rogers et al. 2005). In addition to improvements in several aspects of imitative abilities, interventions targeting imitation have also been shown to have positive effects on various related skills including imitative language (Ingersoll et al. 2006), expressive language (Young et al. 2011), appropriate play schemes (Ingersoll and Schreibman 2006), joint attention (Ingersoll et al. 2011), combined gestures (Ingersoll et al. 2007), spontaneous gestures (Ingersoll et al. 2007), spontaneous language (Rogers et al. 2005), social communication behaviors (Rogers et al. 2005), as well as fine motor, gross motor, and cognitive performance (Dawson et al. 2010).

Imitation is also used as a pivotal component in early interventions that aim to effect change in core deficits of children with autism. One such example is an intervention that targets joint attention, symbolic play, engagement, and regulation (JASPER) in which adults frequently imitate young children's play acts in order to promote social communication (Kasari and Lawton 2010). Imitation is conceptualized as an important adult strategy for helping children achieve better social communication.

Future Directions

Work in the field still aims to determine the centrality of imitation as a deficit in individuals with ASD, and the ways in which imitation profiles differ between individuals on the spectrum. In addition, there continues to be work done to determine which imitation interventions are most

successful in improving imitation skills of young children with ASD, as well as the ways in which these imitation interventions affect other important social communication skills.

Immigrant Status (Epidemiological Studies)

Catherine E. Rice
National Center on Birth Defects and
Developmental Disabilities, Centers for Disease
Control and Prevention, Atlanta, GA, USA

Definition

An immigrant is a person who leaves his or her country of origin to reside in another country. A refugee is a specific type of immigrant who leaves his or her country of origin due to safety threats or out of fear of persecution.

Historical Background

Typically, studies of immigrant status and autism spectrum disorders (ASDs) have examined whether the occurrence of ASDs is the same for children born to a mother or father who was born in another country (immigrant) as compared to parent-child pairs who were born in the same country (nonimmigrant).

Current Knowledge

Most epidemiologic studies of ASDs have been conducted in Europe, North America, and areas of Asia; there is limited information on the occurrence and characteristics of ASDs in other areas of the world. A few studies have raised speculation about increased occurrence of ASDs among children who had at least one parent who immigrated to the country where the child was born (Gardener et al. 2009 for a review). These studies look at the occurrence of ASDs among subgroups within the country being studied and have not included comparisons of ASDs across countries. For example, a few studies in the UK found that Caribbean-born mothers and fathers residing in the UK were more likely to have a child with an ASD than UK-born parents (Goodman and Richards 1995; Keen et al. 2010; Wing 1980). In addition, mothers born in Africa and Asia were more likely to have children with ASDs in the UK; however, European-born immigrants to the UK showed no association (Keen et al. 2010). Studies from Sweden report increased prevalence of ASDs in the group where either parent was not Swedish-born (Gillberg and Gillberg 1996). They also found increased frequency of ASDs among immigrant groups only in urban, but not rural areas (Gillberg et al. 1987). Increased occurrence of ASDs among children born in Sweden was reported for mothers born outside of Sweden (Hultman et al. 2002), among mothers born in Uganda (Gillberg et al. 1995), and if either parent was of Somali descent (Barnevik-Olsson et al. 2010) as compared to Swedish-born parents. Concern about increased prevalence of ASDs among US-born children with parents of Somali descent has also been raised in the USA

(Minnesota Department of Health [MN] 2009). Among children with ASDs born in Denmark, increased association was found for offspring of mothers born outside of Europe or parents born in different countries (Lauritsen et al. 2005) with one study finding an association for mothers, but not fathers, born outside Denmark (Maimburg and Vaeth 2006). Increased frequency of ASDs in New South Wales was noted for children of mothers born outside of Australia, specifically from Asia (Williams et al. 2008). There has also been some indication that the level of impairment may be more severe among parental immigrant groups (Dealberto 2011). Contrary to the hypothesis that parental immigration increases the chances of having a child with an ASD in the new country of residence, a US study indicated that mothers who immigrated from Mexico to California were less likely to have a child with an ASD than Hispanic mothers born in the United States (Croen et al. 2002).

While many of these studies are suggestive of an association between parental immigration status and having a child with an ASD, small sample sizes limit firm conclusions. There are many challenges in evaluating immigrant status including the potential variation and bias in the way immigration status may be documented. This could impact the ability to classify a child as having an ASD among immigrant families. This could also decrease the validity of data on parental birth location and limit the available data on the total population of immigrants by specific countries of origin or ethnicities needed to make reliable prevalence estimates (MN 2009; Fombonne 2003). In addition, there are many reasons why an individual or family may immigrate to another country. Grouping all immigrants together as a homogeneous group may mask some important differences among subgroups. For example, there may be different sociodemographic, environmental, and possibly biological profiles among groups who immigrate for higher education or sponsored employment from those who immigrate based on refugee status or who are undocumented (i.e., not legally registered in the new country of residence). The larger sociopolitical context is also relevant. For example, administrative prevalence

estimates of ASDs among Hispanic children in California vary based on immigration policy changes (Fountain and Bearman 2011).

Several theories have been proposed to account for a difference in the occurrence of ASDs based on parental immigrant status. These explanations include cultural differences in how the features of ASDs are identified and viewed by parents and professionals among different ethnic groups, which may result in differential identification of ASDs among some groups. In addition, there may be disparities in how children are identified. However, contrary to the findings that minority groups tend to be underidentified with ASDs (CDC 2009; Kogan et al. 2009), higher frequency among select immigrant groups indicates the opposite pattern. For some immigrant groups, it could be that having unique status such as a member of a political refugee group enhances identification of ASDs through linkages to service systems available to this population (MN 2009). While several identification mechanisms have been proposed, it is important to consider whether there is a true etiologic difference caused by biologic factors, exposures, or a combination of the two across immigrant and non-immigrant groups. For example, differences in familial relatedness and differential genetic risk for ASDs or other developmental disabilities have been noted, but not well studied (Barnevik-Olsson et al. 2010; Morrow et al. 2008; Ropers 2010). Another possibility is that there is differential migration of people with ASD-like social deficits, resulting in an increased likelihood of their children having an ASD compared to the general population (Fombonne 2005; Gillberg et al. 1995). Hypotheses of differential environmental experiences among immigrant and nonimmigrant groups have also been raised as possible routes to increased risk for ASDs among these groups. These include increased maternal stress (Gardener et al. 2009), exposure to new infectious agents (Gillberg et al. 1995) or environmental neurotoxins such as pesticides (Fountain and Bearman 2011), and differential vitamin D deficiency among groups with skin or clothing that reduces exposure (Dealberto 2011; Fernell et al. 2010).

Future Directions

Multiple studies suggest an increased occurrence of ASDs among children with at least one immigrant parent as compared to nonimmigrant parents. Additional studies with larger samples in different locations would be helpful both to confirm and better understand this possible association. In addition, data on the prevalence of ASDs in the countries of origin (e.g., in Somalia or areas of the Caribbean) would provide useful comparison data. Further attention to the heterogeneity of immigrant populations and whether specific characteristics apply to a group (e.g., refugee status) would also be helpful. In addition, attention to the quality of the data to include case-finding methods that attempt to identify all individuals in a defined geographic area by relevant characteristics (age group, race/ethnicity, parent birth place, etc.) is important. Also needed is a reliable source for the population denominator (base population of people within that immigrant status group). Finally, more careful examination of biologic and exposure differences between immigrant and non-immigrant groups in association with status of having an ASD could be very useful in identifying unique risk factors for ASDs among these populations.

Impact of Race, Ethnicity, and Gender on Social and Behavioral Ratings Within the ADOS

Ashley J. Harrison and Yvette F. Bean
Department of Educational Psychology,
University of Georgia, Athens, GA, USA

Definition

At present, diagnosing autism spectrum disorder (ASD) relies on the identification of symptoms by comparing clinician-observed and parent-reported behaviors to typical and atypical exemplars. Historically these examples reflect behaviors from the most highly researched groups – White, Western, and males (Hilton et al. 2010). Using reference behaviors based on

majority groups discounts the dynamic nature of cultural and social behavior and can inadvertently lead to culture-based biases in ASD measures assessing social constructs. Research has documented cross-cultural variability in a range of behaviors central to ASD diagnosis.

Distinct values about eye contact and varied interpretation guidelines among cultures (i.e., individualist and collectivist countries) result in different gaze topography. The extent of sustained eye contact and regularity of eye contact between adults and children also varies between racial groups in the USA (Fugita et al. 1974). Similarly, cross-cultural differences exist in the amount and type of play, particularly in child and adult dyads (Lancy 2007). Both internationally and among distinct US racial and gender groups, play differences reflect cultural variability in sociocultural gender roles (Lai et al. 2015) and in valuation of attributes like self-assertion (Kochman 1981).

Culture also impacts emotion expression and recognition. Cross-cultural variability in emotion recognition (Elfenbein et al. 2007) is attributable to using unique facial expressions to represent basic emotions across cultures and different facial viewing patterns (i.e., holistic patterns in collectivistic cultures and analytic patterns in individualistic cultures; Masuda and Nisbett 2001). Culture can also impact how different facial features are “weighted” during face processing (Yuki et al. 2007). Culture also impacts nonverbal facial cues used to express emotions, referred to as “nonverbal accents.” Thus, people demonstrate an in-group effect where they recognize emotions from their own culture more accurately (Marsh 2003). Different levels of expressivity between racial groups and gender in the USA (Vrana and Rollock 2002) might reflect distinct values placed on spontaneous expression of feelings (McClure 2000).

Aspects of language with cultural underpinnings, such as pragmatic use, nonverbal communication, and speech patterns are embedded in both social and repetitive/restrictive ASD symptom clusters. Cultures weight verbal and nonverbal messages differently depending on their reliance on context (Knapp et al. 2013) and have differing styles for proximity, volume, and other nonverbal conversational cues (Collett

1971). Cultural variability in pragmatic language impacts important aspects of conversing (i.e., turn-taking, interrupting, humor), as well as frequency of conversation between children and adults (Carter et al. 2005). Cultural variability is also documented in pronoun usage among bilingual individuals (Carter et al. 2005) and grammatical patterns between different US racial groups depending on the English dialect spoken at home (Hall and Freedle 1975).

A failure to account for known variability in these behaviors fundamental to ASD diagnostic assessment could result in meaningful under- or over-pathologizing of behavioral deviations from classic exemplars. One study examined a subset of items from one widely used observation-based ASD diagnostic tool to determine if racial, ethnic, or gender measurement biases existed. After holding overall symptom levels constant, results revealed modest biases in items assessing eye contact, stereotyped language use, and echolalia for racial and ethnic minority groups (Harrison et al. 2017). Although the amount of bias in the sample was small, results highlight the diminished accuracy that could arise through a reliance on narrow, culturally bound definitions of what constitutes typical behaviors and arbitrary clinical thresholds. The tendency to rely on one presentation of ASD is linked to inaccurate identification of autistic females (Kirkovski et al. 2013). Cultural variability in caregiver perception of behavior and personal values can also influence endorsement of problems and, thus, diagnostic outcomes. Taken together, these cultural factors could impact ASD prevalence. Increasing clinician awareness of cultural differences in child and parent behaviors and utilizing rigorous transadaptation strategies for assessments are critical strategies for buffering diagnostic measurement bias.

Inborn Errors of Metabolism

Jessica L. Roesser

Department of Pediatrics (SMD), University of Rochester, School of Medicine and Dentistry, Rochester, NY, USA

Synonyms

Congenital metabolic diseases; Inherited metabolic diseases

Definition

Inborn errors of metabolism are a very large group of genetic or inherited disorders, often due to single-gene defects, that impact the typical function of specific and identified biochemical processes. It is

estimated that they occur in 70/10,000 live births. Metabolism is the act of synthesizing or breaking down compounds and involves biochemical action. When there is a congenital absence of an enzyme or other biochemical impediments to breakdown of cellular by-products or creation of necessary molecules, the intended cellular functions cannot take place resulting in illness or cellular damage. Accumulation of toxic substance(s) may occur. An individual may be unable to create an essential compound. One example of an inborn error of metabolism is phenylketonuria or PKU. This is an autosomal recessive genetic disorder characterized by the absence of an enzyme (phenylalanine hydroxylase) that forms the amino acid phenylalanine ingested through the diet into tyrosine. If untreated, phenylalanine accumulates as a toxic compound and can cause brain damage. Prior to newborn screening programs to identify this disorder and allow for implementation of a special dietary treatment, this was one cause of symptoms of autism and intellectual disability. Inborn errors of metabolism may affect biochemical systems that are responsible for synthesis and/or removal of amino acids, cholesterol and bile acids, creatine, fatty aldehydes, lysosomes, organic acids, peroxisomes, pyrimidines, urea cycle intermediates, and vitamins/cofactors and glucose homeostasis and transport, among others. This class of disorders is often categorized into disorders that impact amino acid, carbohydrate, or organic acid metabolism in addition to lysosomal storage diseases. Newborn screening with mass spectroscopy makes it possible to identify many of these disorders early in infancy. At this time, research studies indicate that evaluation for inborn errors of metabolism in children with nonsyndromic autism is not indicated (Campistol et al. 2016). Measured metabolites suggesting metabolic dysfunction that are not associated with a known inborn error of metabolism could be causative of the symptoms of ASD or may be secondary to either treatments used for ASD or to associated medical conditions. Mutations of genes in the maternally inherited mitochondrial genome appear to cause increased oxidative stress and changes in energy metabolism in the cell. It has been suggested that there is an increased rate of mitochondrial disorders among individuals with ASD.

Incidence

Lisa Croen
Autism Research Program, Kaiser Permanente
Division of Research, Oakland, CA, USA

Synonyms

[Cumulative incidence](#); [Cumulative risk](#); [Incidence density](#); [Incidence rate](#)

Definition

Broadly, incidence refers to newly occurring health events. In the context of public health, incidence may be used to describe new cases of disease, as opposed to chronic or preexisting

conditions. More specifically, incidence is expressed as the number of new conditions measured over a period of time divided by a denominator.

When this denominator is the number of persons “at risk” (free of the condition being studied) at the beginning of the specified period of time, this measure of incidence is called the incidence proportion, the cumulative risk, or the cumulative incidence. Cumulative incidence is often expressed as a percentage. When the denominator is the amount of “person-time” at risk, the measure of incidence is called the incidence density, incidence density rate, incidence rate, or person-time incidence rate. Person-time is a single number which represents the amount of time an entire population was at risk over the prespecified period of time.

Incidental Teaching

Andrea McDuffie

MIND Institute University of California-Davis,
Sacramento, CA, USA

Definition

Incidental teaching is a naturalistic language intervention approach which targets the acquisition of spoken language within the context of naturally occurring adult-child interactions, including play. Incidental teaching requires that the child's environment be arranged to attract the child to interact with toys and activities. Child learning can then be structured and sequenced to take advantage of the child's interests and motivation within these play-based activities. Incidental teaching focuses on child-directed activities, that is, following the child's lead to encourage child motivation to initiate an interaction by requesting help from the adult. Because it is situated within the natural environment, incidental teaching supports the generalization of targeted skills. Teachers/clinicians and parents can use arrangement of the natural environment to indirectly prompt child initiation of teaching episodes which are based upon pre-determined intervention targets or educational objectives. Once the child shows an interest in the activity, by gesturing or requesting, the parent or clinician can prompt an elaborated version of the child's initiation. Natural consequences (in the form of access to desired materials, assistance, or adult attention) are provided consistently to reinforce the child's production of an elaborated communicative attempt. Incidental teaching differs from traditional discrete trial behavioral approaches in that teaching trials are child initiated and the reward for correct language production is directly related to the child's target behavior.

Historical Background

The motivation for the development of a naturalistic language teaching paradigm emerged from

the work of Don Baer at the University of Kansas in the 1970s. Baer's work highlighted the lack of skill generalization that could result from the implementation of highly structured, massed trials using behavior modification techniques. These operant techniques resulted in language behaviors that were under strict stimulus control and failed to generalize to spontaneous use in uncontrolled contexts. Incidental teaching was first introduced by Hart and Risley (1968, 1974, 1975) to teach labels, adjectives, and compound sentences to disadvantaged children within a preschool classroom in which the environment was carefully arranged to motive child initiations. In addition, incidental teaching provides many of the stimulus conditions necessary to support generalization. It is conducted on numerous occasions throughout the day within the setting conditions that maintain natural language use. Additionally, reinforcement contingencies are likely to be less discriminable under incidental teaching, than in one-to-one teaching, leading to enhanced generalization. Because the child controls the instances in which incidental teaching occurs (also known as "teachable moments") and specifies the reinforcers, incidental teaching constitutes "loose training" (training that involves many exemplars in an environment that is not tightly controlled).

Rationale or Underlying Theory

The rationale for the effectiveness of incidental teaching arises from both developmental and behavioral theories. According to behavioral theories, incidental teaching should be effective in teaching language targets in natural contexts because it incorporates the behavioral learning principles of imitation, modeling, shaping, loose teaching, multiple exemplars, and contingent reinforcement. According to developmental theories, incidental teaching should be effective in teaching language targets because it follows the child's lead and teaches to the child's interests and motivations. In addition, there is a close correspondence between the child's focus of attention to an event and the way this event is linguistically encoded by the adult. The selection of developmentally

progressive teaching targets is closely matched to the child's current abilities, and the child is able to observe that his communicative attempts have an effect on the environment by gaining him access to attention, assistance, and child-selected reinforcers.

Goals and Objectives

The goal of incidental teaching is to increase language skills within the natural environment by means of adult-child interactions that resemble those in typical development. The incidental teaching approach is child directed and uses natural consequences to reinforce child communicative attempts.

Treatment Participants

Over the years, incidental teaching has been used successfully with many groups of children who are language delayed. The earliest participants in studies of incidental teaching were children who were economically disadvantaged. The approach was then extended to children with intellectual impairments. More recently, incidental teaching strategies have been examined for use with children with autism (e.g., the Walden Toddler Program). The application of incidental teaching to children with autism was motivated by problems with prompt dependence and generalization that might emerge for children with autism following language teaching based on discrete trial training.

Treatment Procedures

Incidental teaching involves: (1) arranging the environment to increase the likelihood of child initiations (which set the occasion for teaching episodes), (2) selecting developmentally appropriate language targets for the child, (3) responding to child initiations with requests for elaborated language that resemble targeted forms, and (4) reinforcing child communication bids with attention and access to desired materials. Incidental teaching episodes are brief to maintain

child engagement. Incidental teaching differs from naturally occurring language learning by typically developing children in that language targets are preselected by the adult and a sequence of least to most prompts is used. Adapted versions of incidental teaching have introduced the use of time delay procedures and the mand-model technique. Time delay is a procedure in which a brief pause is introduced between a stimulus and a prompt in order to elicit a previously learned response from the child. In the mand-model procedure, non-yes-no questions as well as imitative prompts are used to increase the number of teaching episodes that can be implemented while using an incidental teaching approach. Another modification of incidental teaching is the training of parents to act as their child's interventionist.

Efficacy Information

Many published studies over the last 40 years have demonstrated the efficacy of various versions of incidental teaching procedures in teaching language skills to children with autism.

Outcome Measurement

Outcome measures for studies utilizing an incidental teaching approach typically consist of spontaneous and imitative spoken responses by the child. However, some studies of incidental teaching have also measured children's receptive identification of targeted vocabulary.

Qualifications of Treatment Providers

Incidental teaching has been found to be effective when used by teachers, clinicians, and parents.

Inclusion

Joan Lieber
Counseling, Higher Education and Special
Education, University of Maryland, College Park,
MD, USA

Definition

Inclusion means that children with autism (ASD) learn alongside typically developing children in general education classrooms. For young children with ASD, those classrooms may be community-based child care programs, Head Start, or prekindergarten programs. For school-aged children,

those programs are in their local elementary, middle, or high schools. When children with ASD are included, they have the opportunity to develop relationships and learn from and model the behavior of their typically developing peers (Fein and Dunn 2007). When children with ASD are fully included, they not only have the opportunity to learn academic and functional skills, they become accepted members of their community (Allen and Cowdery 2012).

Historical Background

The term “inclusion” began to appear in the 1990s (Odom and Diamond 1998). Before then, children who received instruction in general education classrooms were mainstreamed. Children who were mainstreamed were in general education classrooms part time. They visited the general education classroom for selected lessons and activities, but their primary placement was still in a special education classroom. The special education teacher was responsible for their educational progress (Mastropieri and Scruggs 2000). That changed in the 1990s with inclusion. Today, children who are included are now placed in general education classrooms, and the general education teacher has that responsibility.

The change from segregated placements to mainstreaming to inclusion came about through a series of laws and court cases with the most prominent being IDEA (Individuals with Disabilities Education Act), passed originally as PL 94–142: The Education for All Handicapped Children Act. This law and its subsequent amendments contain a number of provisions, which have provided the basis for educating children with ASD in inclusive environments. Among those provisions are zero reject and least restrictive environment. Zero reject sets forth the basic principle that children with disabilities cannot be excluded from receiving a public education. Least restrictive environment states that, to the maximum extent possible, children with disabilities should be educated with their peers who do not have a disability. Another law, the Americans with Disabilities Act (ADA), has also had an impact on

children being served in inclusive environments. The ADA has had a particular impact on young children because ADA stipulates that children cannot be excluded from child care programs unless their presence affects the health or safety of other children (Grisham-Brown et al. 2005).

There are additional arguments that support the education of children with disabilities in inclusive environments that include moral and rational reasons (Bailey et al. 1998). From a moral perspective, children with disabilities have the same right as other children to participate in programs and activities. Further, it is just the right thing to do. From a rational perspective, children with disabilities benefit when they interact with typically developing children because they can learn new skills from them. Typically developing children benefit as well because they learn about differences among people and may become more accepting of people who are different (Bailey et al. 1998).

Current Knowledge

According to Harrower and Dunlap (2001), there have been relatively few studies which have investigated inclusion as the independent variable, that is, few which ask the question if children with ASD perform better socially and academically in inclusive classrooms than they do in segregated classrooms. However, as Harrower and Dunlap suggested, the better question to ask is how can children with ASD receive the help they need to be successful in an inclusive classroom? Inclusion cannot be accomplished successfully if the adults who work with the children with ASD in their classroom are not prepared for that challenge.

The Role of Teachers in Inclusive Classrooms

There are a number of ways that general education and special education teachers can work together to provide instruction for children with ASD. One approach is coteaching (Friend and Cook 2007). In coteaching, a general education teacher and a special education teacher are classroom equals. They plan together and make decisions about

how learning can be optimized for all the children in the classroom. The general education teacher is the curriculum expert; the special education teacher knows how to differentiate instruction so that children with ASD can learn as well. Coteachers can use a number of approaches to ensure that all children are engaged during instruction. They include one teaching and one observing, station teaching, parallel teaching, alternative teaching, teaming, and one teaching and one assisting (Friend and Cook 2007). In all the approaches, it is important to be sure that the special education teacher does not get relegated to the role of a classroom assistant who is only there to help out.

Paraeducators

Another approach to fostering inclusion for children with ASD is to assign a paraeducator to them in the classroom. This approach is used frequently with children with ASD because they often have intensive needs. The paraeducator works under the supervision of the special education teacher who plans the specific instruction. The paraeducator's role might include providing alternative instruction within the general education classroom, modifying and simplifying the response that the child with ASD is expected to provide, providing reinforcement when the child with ASD makes an appropriate response, and collecting data on child progress (Friend and Cook 2007). It is important that the teachers in the classroom ensure that the paraeducator does not become a "Velcro" aide. If the paraeducator is always attached to the child with ASD, the benefits of being in an inclusive classroom disappear because the child does not have the opportunity to learn from other children.

General Approaches to Inclusion

Regardless of the age of the children with ASD, their inclusion into general education classrooms and activities can be facilitated if the curriculum incorporates elements of Universal Design for Learning (UDL). A UDL curriculum focuses on creating learning environments and adopting practices that give children a variety of formats for responding, demonstrating what they know, and expressing ideas, feelings, and preferences

(Center for Applied Special Technology [CAST] 2004). The three key principles of UDL are multiple means of representation, multiple means of engagement, and multiple means of expression (CAST 2004). Teachers who use *multiple means of representation* provide their instruction using a variety of formats for children who may need actual objects, pictures, or text to understand the content that the teacher presents. When a curriculum is designed using UDL principles, children are given the opportunity to use *multiple means of expression* for their responses. Some children may make written responses or respond using language. Others may use gestures or PECS or other assistive devices to demonstrate what they know. A curriculum that includes *multiple means of engagement* has activities and lessons that are interesting to all children; they are engaged and interested in participating and learning (Blackhurst et al. 1999; CAST 2004; Orkwis 2003). Having a curriculum that incorporates elements of UDL is particularly valuable for children with ASD who are included in general education classrooms.

Inclusion in Early Childhood Classrooms

The importance of including young children with disabilities in all early childhood classrooms has been supported by two major early childhood organizations, the Division for Early Childhood (DEC) and the National Association for the Education of Young Children (NAEYC). These organizations published a joint statement on inclusion in 2009. This position statement argues that children can be included successfully if they have access, can participate, and are provided with supports. Access comes through the design of the program and the environment; participation occurs when teachers use a variety of approaches including routine-based teaching and explicit interventions; and supports happen when the administration, teachers, related service providers, and families collaborate to ensure children's success (DEC/NAEYC 2009). More recently, in 2015, the U.S. Department of Health and Human Services and the U.S. Department of Education issued a Policy Statement on Inclusion of Children with Disabilities in Early Childhood Programs.

Included in this policy statement is: (1) the expectation that inclusion in early childhood programs be of high quality; (2) that there are legal and scientific reasons for inclusion; and (3) identification of free resources for States, LEAS, schools, and early childhood programs to support high quality inclusion (HHS/ED 2015, p. 1).

Young children with ASD are eligible to receive services as soon as they are identified. Children before the age of three are typically served in their homes, but they may receive services in other natural environments like a child care center. Once they turn three, however, most attend programs with other children and may be included in a variety of programs. Children with disabilities have been included in Head Start since 1972 with the passage of PL 92-424. Beginning in 1972, Head Start programs have been required to ensure that 10% of the children they serve have disabilities (Grisham-Brown et al. 2005). Although many Head Start programs serve children with more mild disabilities such as speech/language disabilities, some children with ASD are included. Young children with ASD may also attend state-funded prekindergarten programs and community-based child care programs.

In order for young children with ASD to learn and thrive in inclusive programs, the first step is to ensure that the program is of high quality. According to Sandall and Schwartz (2008), a high-quality program provides a consistent schedule that is divided into time segments that are appropriate for young children, has a combination of large group and small group activities as well as time for children to play and work alone, has activities that teachers lead and those that are child-directed, allows children time for outdoor play and routines such as toileting and eating, has both quiet times and active times, and finally, maximizes the time that teachers teach and minimizes the time that children wait.

Having a high-quality program is only the beginning. In order for children with ASD to learn both academically and socially, the teachers need to be ready to make modifications to the curriculum. In their Building Blocks model, Sandall and Schwartz (2008) described eight curriculum modifications: environmental support,

materials adaptation, activity simplification, child preferences, special equipment, adult support, peer support, and invisible support. Because young children with ASD are typically delayed in their language and social development, a number of these modifications can be particularly useful as teachers include them in the ongoing classroom routine.

Barton et al. (2011) described how curriculum modifications can help a child with ASD participate successfully in circle time, a large group activity that is standard in most early childhood classrooms. Circle time is a teacher-led activity that is used to teach early literacy activities through book reading, time concepts through reviewing the daily routine and calendar, as well as music and movement activities. Barton et al. suggested that circle time can be particularly challenging for children with ASD because during circle time, children are required to attend to a teacher and follow teacher directions, to be next to other children, and to use language to communicate. However, it can be a valuable activity because it provides an opportunity for children with ASD to address skills that they have most difficulty mastering. Barton et al. provided a number of examples of how the curriculum modifications can be used for children with ASD during the circle time activity. If children have difficulty making the transition from another activity to the circle, the teacher can use child preferences and allow the children to bring a favorite toy with them to the circle. Children can hold on to that toy throughout the circle activity. Once children are seated at the circle, the teacher can reduce the distractions that come from the shelves of toys that surround the circle area by covering those shelves with fabric that drop down during circle time. The teacher can adapt the materials used during circle by creating a daily schedule that incorporates words and pictures to symbolize parts of the daily schedule. In another adaptation, as the teacher reads a book, the children can have their own smaller version of the book to follow along with. Peers can be used to support the children with ASD in a variety of ways. Children with ASD can sit next to a favorite peer, the peer can go

first when the teacher asks a question so that the children with ASD have a language model to follow, and the peer can even prompt the children with ASD to make a response. These curriculum modifications can be used throughout the daily routine for other large group as well as small group activities.

In addition to curriculum modification, children's learning is enhanced in inclusive classrooms when teachers embed children's learning objectives within the context of ongoing classroom activities (Sandall and Schwartz 2008). If a child with ASD has an IEP objective to enhance expressive language by making requests that objective can be targeted during many activities throughout the day. During snack time, the child can be asked to request juice, cookies, and fruit. And children are naturally reinforced when given the food they asked for.

Inclusion for School-Aged Children

Sandall and Schwartz (2008) described a general approach to adapting instruction that can be used across curricula in early childhood classrooms to promote effective inclusion for young children with disabilities. Harrower and Dunlap (2001) similarly discussed general instructional strategies that have been shown to be effective in improving social and academic outcomes and that can be implemented in inclusive settings for school-aged children.

A number of the approaches that Harrower and Dunlap (2001) described involve peers. One approach is peer tutoring in which a typical peer provides assistance, instruction, and feedback to a child with ASD. Another approach, that involves larger groupings, is cooperative learning. In cooperative learning, small groups of children work together to learn information. Small groups allow children with ASD to participate more frequently than they could in a large group, teacher-led activity. More frequent participation leads to higher levels of engagement with the material. Cooperative learning also allows the children with ASD to engage in social interactions with their peers while learning academic content. Handleman et al. (2005) listed other

peer-focused interventions that have been used successfully in inclusive classrooms. These include having a peer buddy system for all children in the classroom and instituting social skills groups.

A second group of approaches that Harrower and Dunlap (2001) identified are self-management strategies. According to Harrower and Dunlap, these strategies help children with ASD become more independent which allows them to operate more effectively in an inclusive classroom. As children become more independent, teachers can spend more of their time providing instruction to the class. Harrower and Dunlap (2001) provided additional strategy categories including antecedent procedures and delayed contingencies. These approaches are designed to help children with ASD become less dependent on adults so that they can operate more effectively in inclusive classrooms where there are fewer adults and more children.

Because general education teachers are responsible for the instructional content in inclusive classrooms, they can foster the participation of children with ASD by ensuring that the content is meaningful to all of the children, by having a range of materials to teach the content, and by using a variety of lesson formats (Kluth 2010). These methods incorporate elements of UDL and make the content accessible to a wide range of learners.

Future Directions

Although children with ASD have been included in general education classrooms for over 20 years, there are a number of areas that need further investigation. These areas include:

- Effective strategies for middle and high school students with ASD in inclusive settings
- How best to train general education teachers to provide instruction for children with ASD
- Strategies to enhance collaboration between general and special educators who work with children with ASD

Definition

1.0% to 2.64% of children are estimated to have a diagnosis of autism spectrum disorder (ASD) with an increasing number of individuals receiving a diagnosis of ASD (ASD; Baio et al. 2018; Baron-Cohen et al. 2009; Boilson et al. 2016; Kim et al. 2011; Wing and Potter 2002). Given this increase, there is a growing demand on diagnostic and intervention services (Shattuck and Grosse 2007; Wise et al. 2010), and parents of children with ASD report that they are not receiving the disability services that they need (Jones et al. 2017). Furthermore families with a child with a diagnosis of ASD report feelings of social isolation and feeling cut off from the wider society (Byrne et al. 2018; Woodgate et al. 2008).

Given families with a child with ASD often face long wait lists for intervention in public disability services and report not receiving needed

services (Jones et al. 2017; Rivard et al. 2014), exercise interventions outside the clinic could be a worthwhile alternative. Moreover there is research to suggest that providing social skill promotional activities in a child's natural setting appears to be more effective than traditional clinical settings (Bellini and Peters 2008).

It is necessary to distinguish structured exercise from physical activity. While there are many definitions of exercise and physical activity, Caspersen et al.'s (1985) interpretation shall be employed for the purpose of this definition. Physical activity is defined in a broad term as any movement of the body, created by the body, that results in energy expenditure, (p. 126), which can be interpreted as movements that are required in everyday life such as climbing stairs, cleaning, etc. Caspersen et al. (1985) define exercise as a purposeful, planned activity that is repetitive in nature and has set goals pertaining to the improvement or maintenance of physical fitness (p. 128). Therefore, structured exercise has a clear start and finish time. Given individuals with autism spectrum disorder (ASD) have greater difficulties coping with unstructured time than their typically developing peers, there is benefit to be sought from structured exercise (Van Bourgondien et al. 2003).

The inclusion of disabilities within exercise is neither a new nor novel idea as Block and Obrusnikova (2007) reviewed 20 years of studies highlighting the success of inclusion of children with disabilities in a supported physical education environment. Furthermore, there is converging evidence to suggest that the benefits of structured exercise in children with ASD extend beyond general physical health and have a positive impact on their social development. Ohrberg (2013) described structured exercise in the lives of children with ASD as essential, emphasizing that it allows children to develop interpersonal skills through engaging in fun activities with peers in a very normal way (p. 53).

There is converging evidence to suggest that structured exercise and inclusive physical education classes improve social interaction and promote social development in students with ASD (Foti et al. 2014; Pan et al. 2011). Structured cycling, swimming, and martial arts programs

have reported improvements in self-efficacy and social interaction and a reduction in antisocial behaviors in children with ASD (Movahedi et al. 2013; Pan 2010; Todd et al. 2010).

However, the core characteristics of autism spectrum disorder (ASD), which include impairments in social communication and interaction, and the presentation of restricted, repetitive behaviors (American Psychiatric Association [APA] 2013) may conflict with the expectations of exercise (Jones 2003; Obrusnikova and Cavalier 2011; Pan 2014; Srinivasan et al. 2014). Such a conflict may explain why children with a diagnosis of ASD are not meeting the recommended exercise guidelines (Pan and Frey 2006). Furthermore, children with ASD are reported to be less active during breaktime and engage in few physical activities for shorter periods of time when compared with their typically developing peers (Bandini et al. 2013; Healy et al. 2013; Hilton et al. 2008; Pan 2008). Moreover, parents and teachers report being unaware of the many inclusive structured exercise programs for children with ASD (Srinivasan et al. 2014).

The social model of disability guides the rationale and success of inclusive sport programs. The social model welcomes diversity, including and valuing each adolescent and providing a liberating perspective on disability, relocating the disability into the structures of society and outside of the individual. The restrictions that people with impairments face in sport can be readily observed, and challenged, through the social model, from individual attitudinal and institutional prejudices to inaccessible sporting facilities, exclusionary policies, or unusable transport systems (Oliver 2004). Mike Oliver (2004) argued that the social model has the power to “transform consciousness” (p. 42) by connecting personal experience to professional practice.

Despite these benefits, sport is an area which is still governed by the medical model of disability (Townsend et al. 2016). The medical model of disability would suggest that people are disabled by their impairments or differences. The medical model looks at what is “wrong” with the person and not what the person needs, and it can create low expectations which can lead to people losing

independence, choice, and control in their own lives.

In light of the medical model of disability, the provision of inclusive opportunities still has a low priority in community recreation and sport in many countries (Storey 2004) causing individuals with additional needs to take part in sporting activities much less frequently than other people with disability and those who do not have a disability (Darcy and Dowse 2013).

A lack of coaching expertise specific to disability and adaptations has been identified as a barrier for the participation of adolescents with additional needs in sport (D. B. Jones 2003; Kozub and Porretta 1998; Tsai and Fung 2009). Coaching is a vital aspect of athletic development and success, and as such, coaches play an important role in facilitating, encouraging, and guiding participation (Erickson et al. 2008; Martin and Whalen 2014). Coaches report very little inclusion of information specific to disability in the accredited training courses for their specific sport (Wareham et al. 2018). Moreover, coaches report the necessity of familiarization with the biological and physiological effects of their athletes’ impairment(s), highlighting that it was left to them to source this information. There is some evidence to suggest that factors such as insufficient knowledge of, or experience with, disability are contributing factors to the reluctance by many coaches to make the transition to coaching athletes with additional needs (Martin and Whalen 2014).

There is a need to develop localized theoretical frameworks to inform initiatives going forward (Edwards 2015). Research suggests there is an absence of participant experiences and perspectives of inclusive sport (Levermore 2010; Rich et al. 2015) and in particular hearing the voices and viewpoints of people with disabilities (Wickman 2015).

Future research should focus on how adolescents with autism spectrum disorder (ASD) can be integrated and included within community sporting clubs with the potential focus sport to be rowing. Such research should obtain the perspective of the main stakeholders regarding the facilitation of an ASD inclusive community club.

These stakeholders would be community club coaches, parents, adolescents with ASD, and typically developing adolescents involved in the club.

Ohrberg (2013) advises on the development of a handbook to facilitate an autism-aware culture in sport. Therefore the input from the stakeholders would potentially be compiled to produce a handbook to facilitate the participation of adolescents with ASD (i.e., identifying potential barriers to participation and sport-specific coaching content to aid understanding of ASD and the subsequent and necessary adaptations to coaching style and training program). This handbook would be introduced and piloted with local clubs and adjusted based on subsequent feedback. This handbook would then be introduced into the national coaching training course as an independent module. The handbook would be edited one further time based on national feedback before being submitted to national sporting body. The proposed handbook would inform a sport-specific framework which encompasses the perspective of all relevant stakeholders, including the adolescent with ASD.
